SIR,—The ætiological significance of bacteria found on sputum cultures in bronchial infection is difficult to appraise, as you suggested in your leading article of March 14, which mentions some of our observations.[1]

To determine the bacteriological cause of chronic bronchitis or bronchiectasis is especially difficult when numerous colonies are found on blood-plates. Since the bacteria that produce chronic bronchial infection may also be found in sputum cultures from patients whose expectoration is entirely allergic in origin—for example, the viscid expectoration of patients with asthma due to ragweed pollen—emphasis has been placed on the presence of gross pus or polymorphonuclear leucocytes in sputum smears, in the belief that bacterial infection is more probable only under these circumstances.

We have assumed the pneumococcus to be the cause of both acute and chronic bronchial infections when a purulent sputum becomes mucoid at the same time as the organism disappears from the culture. In cases in which a prolonged symptomatic remission follows antibiotic treatment, the pneumococcus found before treatment does not generally appear on sputum cultures, except when an acute reinfection occurs.

The *Staphylococcus aureus*, however, does not, in our experience, follow the same pattern. This organism has been repeatedly found on cultures over a period of two to nine years, especially in cases of bronchiectasis. Antibiotic treatment, either by aerosol, penicillin, or the broad-spectrum antibiotics, has often been followed by conversion of sputum from purulent to mucoid, with temporary disappearance of the organism on culture in some cases; in others, *Staph. aureus* may still be present, though in a less abundant growth than before treatment. *Staph. aureus* appears to be the only gram-positive organism that has developed resistance to penicillin and often to terramycin; under these circumstances, the sputum becomes grossly purulent, with abundant growth of staphylococci on blood-plates. When the organism is eradicated by penicillin aerosol (1 million units daily) or by carbamycin, its importance in these cases is demonstrated, provided symptomatic improvement is also noted.

Streptococcus viridans has seemed to us to be pathogenic in cases of chronic bronchial infection in which disappearance of this organism was accompanied by a decrease or elimination of pus in the sputum and by clinical improvement. In some of these patients, the stoppage of antibiotic treatment was followed by reappearance of purulent sputum with apparently the same organism again found in abundant growth on blood-plates. But our therapeutic programme may have suppressed a *Hæmophilus influenzæ*; though this organism did not grow it may have been responsible for some of these cases.

In the treatment of patients with bronchiectasis by aerosol penicillin continued for two to nine years, the sputum may be predominantly mucoid with few or a moderate number of polymorphonuclear leucocytes on smear, and, on culture, a variety of gram-negative organisms without, however, evidence of active infection. When invasion by gram-negative organisms, such as *Bacterium pneumoniæ*, does take place, as shown by purulent sputum and symptoms of bronchial infection, the broad-spectrum antibiotics are generally effective in eliminating this secondary infection. The use of the broad-spectrum drugs is also valuable in the treatment of acute infections with the common gram-positive bacteria, but prolonged treatment of chronic respiratory disease may result in new infections with bacteria previously known more as contaminants than pathogens—namely, proteus, *Bact. aerogenes*, *Pseudomonas pyocyanea* and colon and paracolon bacilli.

Since *Hæmophilus influenzæ* is at times the cause of chronic bronchial infection (though found less commonly in our cultures than reported by Mulder et al.[2]) the latest antibiotics, carbamycin and erythromycin, assume increasing importance. These drugs are now preferred to broad-spectrum drugs, primarily because they do have a more limited range—i.e., against gram-positive bacteria. Furthermore, carbamycin and erythromycin seem to be generally effective in infections due to staphylococci resistant to penicillin and terramycin. In addition, the increasing incidence of allergic reactions to penicillin encourages the trial of these agents in place of penicillin for bronchopulmonary infections with gram-positive organisms. Our knowledge of the part played by the bacteria that are found in sputum cultures may be increased by the use of drugs of limited range, rather than broad-spectrum antibiotics which are effective against both gram-negative and gram-positive organisms.

It is evident that further investigation is required to determine with precision the rôle of the various organisms in maintaining chronic bronchial infection. The interpretation of sputum cultures calls for smears, stained from the same sputum and examined for polymorphonuclear leucocytes. The correlation between the disappearance of pus and the disappearance of bacteria on culture does not always give the bacteriological answer, but this approach, combined with the clinical result, seems to offer more promise than any other. Admittedly, at times, a contaminating organism, such as proteus, may overgrow a blood-plate and obscure the true cause such as a staphylococcus. This seems to have happened in three of our cases in which penicillin was effective in clearing pus from the sputum; although in vitro the proteus organism was highly resistant to penicillin.

New York. ALVAN L. BARACH.

THE EXPERT WITNESS

SIR,—The position of the expert witness was discussed in your annotation of Jan. 10, and it has been caustically satirised by A. P. Herbert.

In a recent case the court heard two expert witnesses, both psychiatrists of consultant status, giving directly conflicting opinions on vital points, particularly with reference to the question of insanity under the McNaughten rules. That the McNaughten rules themselves constitute an archaic and unsatisfactory yardstick for the assessment of insanity is irrelevant at the moment. As a medical (non-psychiatric) witness in this case, I myself found considerable difficulty in forming a sincere opinion of the accused's mental state after evidence had been given on this matter. How great must have been the confusion in the minds of the jurymen?

Surely the time has come—is indeed overdue—for the establishment of court experts or panels of experts, medical and otherwise, owing allegiance to neither Crown nor defendant but trying to assess the difficult technical problems which arise, according to their merits. Clearly the present system can only bring public ridicule to our profession and embarrassment to jurymen, and generally impede the execution of what is in many other ways one of our incomparable assets—British justice.

Department of Pathology,
University of Belfast. A. L. WELLS.

deficiency can fail to produce thyroxine,* at any time in the patient's life, owing to the exhaustion of the completely disordered gland. When an iodine deficiency goitre has been present in more than one generation, the thyroid of the fœtus may be thus early exhausted, and the child will in consequence be born a cretin with a large degenerate goitre. The enlarged thyroid of iodine deficiency has been shown by radioactive studies to be avid for iodine. Atrophy of the thyroid may also be associated with endemic cretinism, and de Quervain (1924) observed that retardation of development (in all systems except the central nervous system) was greater in cretins with atrophic thyroids than in cretins with goitres. This introduces the useful notion, supported by several other clinical observations, that the deficiency of thryoxine production may be quantitative, and that a relative insufficiency does occur. Endemic cretinism must be rare in England, but Murray et al. (1948) referred briefly to two families in which endemic cretinism may have occurred.

Sporadic cretinism or hypothyroidism is rarely associated with a goitre. Still more rare is *familial cretinism* (outside endemic goitre regions), and it appears from the published reports that these cases are associated with a goitre.

Lerman et al. (1946) described two cretinous brothers, both with goitres. Biopsy specimens of the thyroid glands showed areas of hypoplasia. The uptake of radioactive iodine was high, and the concentration of iodine in the removed thyroid was low.

Stanbury and Hedge (1950) reported from Boston the investigation of four cretinous children in one family. The parents were first cousins and their first three children were not hypothyroid, nor had they goitres. The succeeding four children were all goitrous cretins. As a result of radioactive iodine studies Stanbury and Hedge conclude that the thyroids of their patients could extract iodide from the blood but could not incorporate it into thyroxine.

McGirr and Hutchison (1953) describe the results of their radioactive iodine investigations in seven children with goitrous cretinism from three related families and in two half sisters of a fourth family, and conclude that their patients could link iodine to protein and release it into the circulation in an organic form which was not thyroxine. They postulate an intrinsic defect in the final synthesis of the thyroid hormone which is sometimes familial.

I describe here a family of four cretins. In the thyroid gland and in the plasma of the eldest girl the presence of thyroxine was shown, and radioactive iodine studies in the second cretin, a boy, have shown an overactive gland capable of taking up iodine, binding it to protein, and releasing the protein-bound iodine into the circulation.

These four children, G. W. K., G. K., P. K., and J. K. (fig. 1), were first sent to the hospital when their ages were 17 years, 13 years 4 months, $8^1/_2$ years, and $6^1/_2$ years.

Their father and mother are not related. Their father was born at Bentley, Yorks, and their mother at Shirebrook, Notts. The father is an engineer, and the mother worked, before her marriage, on farms at Reddington, Mansfield, and Retford. In all these farms the drinking-water came from a well. Neither parent has had a goitre at any time, nor has there been any thyroid disorder in either of them or in their families. The father has eleven siblings, all of whom are healthy, and his father and mother had no relevant diseases. The mother has three siblings, all of whom are well. The father's height is 5 ft. 3 in., and the mother's 5 ft. 1 in.; in the appearance of neither is there any suggestion of hypothyroidism.

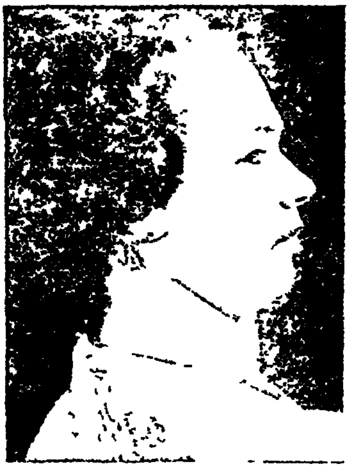

Fig. 2—Profile of G. W. K., showing degree of thyroid enlargement when all thyroid therapy had been stopped for six months.

The family has not lived in an area where goitre is endemic, nor is there anything in the history which suggests the implication of a goitrogenic substance.

---

* For the sake of convenience "thyroxine" will be used to indicate the active secretion of the thyroid gland. It is not intended to imply that other substances, such as triiodothyronine (Gross and Pitt Rivers 1952), may not be active.

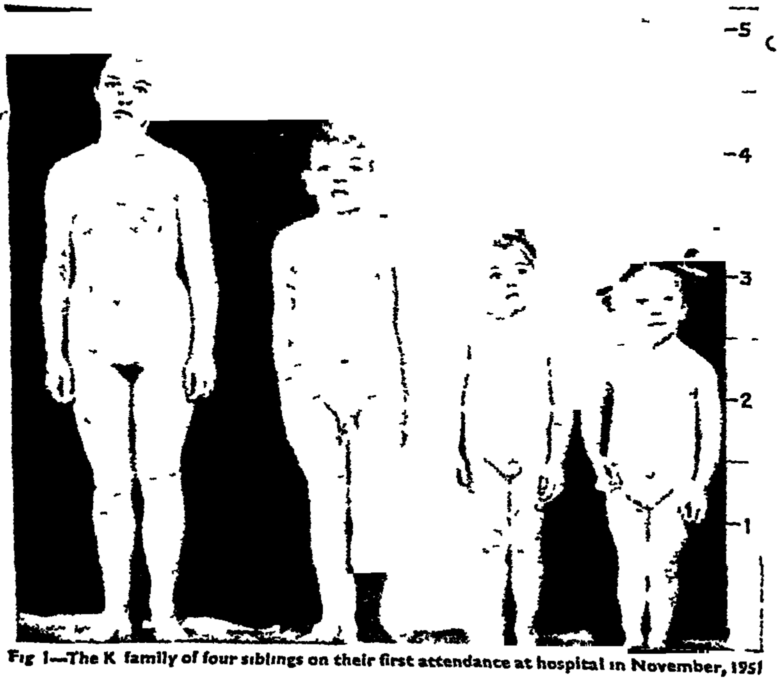

Fig. 1—The K. family of four siblings on their first attendance at hospital in November, 1951.

CASE-RECORDS

G. W. K.—Female, aged 17 (fig. 2). Hypothyroidism was probably diagnosed at the age of 8 years. She is said to have walked and talked at 2 years. She could not read at the age of 7 years but could count up to ten; her intelligence quotient was then reported to be 69%; her height was $36^1/_2$ in. (more than 20% below average). She continued to take thyroid gr. $^1/_2$ thrice daily until May, 1951, when her mother noticed that the neck was swelling. The thyroid therapy was stopped, and the swelling increased steadily in size. Her menses began at the age of 14 and are regular.

When she was examined on Nov. 17, 1951, her facial appearance suggested myxœdema. Her voice was harsh, her intonation guttural, and her speech slow. Her thyroid gland was large and nodular. Her height was 4 ft. 8 in. at 17 years.

Blood cholesterol was 316 mg. per 100 ml., and the basal metabolic rate (B.M.R.) was −23%.

Blood count.—Red cells 4,300,000 per c.mm.; Hb 12.1 g. per 100 ml.

Radiography.—The scale epiphyses of ischium and ilium had not appeared. This retardation, together with evidence elsewhere, gave a bone age of 15 or 16 years.

Electrocardiography showed low voltage throughout, with well marked flattening of P and T waves in all leads.

LOCALISED MUSCULAR ATROPHY IN DIABETES

SIR,—I read with some interest the article by Dr. Hirson (May 16). I have been interested for some time in insulin lipodystrophy, and it appears to me that he is in fact describing the very common condition of insulin fat atrophy. His conclusions are largely drawn from the fact that the areas of atrophy are not "habitually" used for insulin injection by the patient. This is, of course, no proof that these atrophic areas are not in fact directly due to insulin, because even one or two insulin injections, particularly early in the régime, may give rise to quite definite atrophy many months later. In his case 3, I agree that the area over the right masseter is unlikely to have been used for insulin injection, but is it not possible that this is an area of ectopic fat atrophy, which, as he states, has been described by observers in the past? It also appears rather unlikely that, in the case of long skeletal muscle, atrophy would present itself as small elliptical or circular areas; surely one would have expected atrophy to have occurred in the longitudinal axis of the muscle? The photographs he presents are in fact fairly typical of pronounced insulin fat atrophy.

It is possible that a series of biopsies taken from these areas might have helped to prove his case of muscular atrophy, but I feel that it is highly probable that they would show the presence of a fat atrophy without involvement of muscle.

Sheffield. J. N. HARRIS-JONES.

ALCOHOL AND THE MOTORIST

SIR,—At the international conference on alcohol and traffic, held at Stockholm in 1950, Dr. A. Simpson Wells, a South African representative, stated[1] that "recently legislation has been passed in the Union of South Africa permitting a medical officer to take samples of blood to determine the blood alcohol concentration . . . the consent of the driver involved in the accident is not necessary." This statement was quoted in the *British Journal of Addiction* in 1950,[2] and again in your correspondence columns in 1951,[3] when Dr. Pullar-Strecker said:

> "According to Dr. A. Simpson Wells, the Union of South Africa has quite recently added to its legal code a law which permits a medical man to take a sample of blood from anyone who is suspected of being under the influence of alcohol and who has been involved in a road accident. This is quite an innovation; as recently as 1949 attention was drawn to the fact that chemical tests for determining intoxication have never been used in South African courts, because of the common-law principle which protects the accused from giving any evidence which may incriminate him."

Since my return to the Union of South Africa, I have drawn the attention of a representative of the Attorney-General's office to the above statements, and with his permission I quote his comments:

> "The above statements are incorrect. There has been *no recent* legislation permitting the taking of a sample of blood. What happened was that there appeared last year (1952) a Bill which set out a proposed amendment to the Criminal Procedure Act; this amendment would have provided for the taking of blood samples. Unfortunately this Bill was not proceeded with, and the amendment never became law.
>
> "Though there has been no recent legislation and, while there is no specific provision for the taking of blood, I have always held the view (which I know to be shared by at least one counsel of repute) that under present legislation this can be done.
>
> "Sec. 2 (1) Act 39 of 1926 provides that a medical officer of a gaol or any district surgeon may take such steps as he may deem necessary in order to ascertain whether the body of any person . . . shows any condition. I take it that drunkenness is a condition of the body, and if so then to my mind the district surgeon is entitled to take a blood sample to enable him to ascertain that condition. I may add that I have never been able to persuade a district surgeon that he has the power!"

I am bringing the above to your attention, because it is my opinion that the taking of blood samples to determine the degree of intoxication is of a significance analogous to that of X-ray examination in the case of bone injuries —i.e., sometimes confirmatory and sometimes even conclusive.

Johannesburg. J. J. PRAG.

INACCURACY IN THE LABORATORY

SIR,—In the last few years there has been an increasing appreciation amongst clinical pathologists of the extent to which quantitative laboratory investigations may be inaccurate. In your leading article (March 7) you discuss some aspects of the problem. Dr. Harrison (April 18) suggests that the calibration of glassware, especially of pipettes, and the purity of chemicals are important causes of the errors.

We use grade "B" glassware as a routine and repeated checks in the past have not shown serious errors. Dr. A. Pomerance and Mr. D. A. Podmore have carried out a special examination of 22 pipettes taken at random from those in daily use, with the following results:

(1) *Bulb pipettes* (*one mark*).—15 pipettes (capacity 1–20 ml.).

Amount delivered excessive: 9 pipettes (range of error + 0·09 to + 0·8%; mean error + 0·28%).

Amount delivered deficient: 6 pipettes (range of error − 0·05 to − 0·8%; mean error − 0·40%).

(2) *Straight pipettes calibrated throughout the whole length.*—7 pipettes (capacity 1–25 ml.) on which 16 tests from one mark to another were carried out (amounts delivered 1–10 ml.).

Amount delivered excessive: 5 tests (range of error + 0·06–1·4%; mean error + 0·86%).

Amount delivered deficient: 11 tests (*range of error* −0·16–1·4%; *mean error* −0·67%).

These results make it seem unlikely that inaccurate glassware is responsible for the variation which Dr. Wootton and Professor King found between the results of different laboratories (March 7).

Many reagents can now be prepared from chemicals of known standards of purity; experience suggests that these standards are reliable. It is unlikely that lack of purity of chemicals is causing gross inaccuracies.

There are other causes of error to be considered. Many laboratories use accurate, but unsuitable, glassware with resultant loss of accuracy in the manipulations; the straight, calibrated pipettes, tests with which are described above, are a good example. In the choice of suitable glassware the studies of Professor Conway[1] deserve more attention than they have received.

For several years control solutions and bloods have been exchanged between two laboratories in Sheffield and one in a neighbouring town; the results have shown a good deal of variability although the methods have been carefully studied. I have found it impossible to resist the conclusion that the biggest errors are caused by lack of care in the various manipulations; confirmation of this view has been provided by replicate determinations. Better results are obtained by experienced staff and by staff who are not harassed and overburdened with excessive work.

Quantitative laboratory methods have been studied extensively, but the results are scattered through the literature; much remains to be done. Published methods frequently demand considerable modification before they are applicable: the laboratories concerned may not have the time to undertake the necessary studies, and there is uncritical use of the methods without adequate controls. Clinical pathologists need to have at their disposal detailed accounts of well-tried methods

[1] Conway, F. J. Microdiffusion Analysis and Volumetric Error. London, 1950.

Electro encephalography (Dr. F. Graham Lescher) showed in all channels slow activity of raised amplitude and varying from 2 to 6 cycles per sec.

Treatment and Progress.—The thyroid gland was removed by Mr. J. R. Ratcliffe in January, 1952 (see below). The patient has lost the appearance of myxœdema with a dose of thyroid gr. 1 twice daily. Her voice remains guttural. Her blood cholesterol level has fallen to 125 mg. per 100 ml. Electrocardiography now shows normal voltage. She has grown 2 in. in a year. She is well and working happily as a polisher in a pencil factory.

G. K.—Male, aged 13 years 4 months. Birth weight 10 lb. He walked at 2 years. There were other evidences of physical and mental retardation, but his mother did not notice anything wrong. He was aged 4 years 4 months when his sister's hypothyroidism was diagnosed; he was taken to the school clinic, and cretinism was also diagnosed in him. There is no evidence that enlargement of the thyroid gland was observed. Thyroid therapy was started with gr. $^1/_2$ daily; the daily dose was later increased to gr. 1 and gr. $1^1/_2$ alternately. He attended the clinic till 1948, when attendance ceased.

In November, 1951, his appearance was hypothyroid. He disliked cold weather and was wearing two woollen sweaters. His voice was harsh and his speech guttural. His extremities were cold and pale. His height was 48.5 in. (average height for his age 59.8 in.). This represented a retardation of more than 20% and a height age of 7 years. The ratio of upper segment to lower segment was 1 : 1. His weight was 73 lb. (average for age 100 lb.). His head circumference was 22 in. and the length of his penis was 3 in. Both testes were in the scrotum. There was a small soft enlargement of the thyroid gland, which was just visible.

Blood cholesterol level was 266 mg. per 100 ml.

Blood-count.—Red cells 4,500,000 per c.mm.; Hb 82%.

Radiography showed no olecranon process in the ulna and no trochlear centre in the humerus; the bone age was 9 years.

Electrocardiography normal except for a conduction defect in lead V_1.

Electro encephalography (Dr. F. Graham Lescher) gave an abnormal record with much slow activity, 5–6 cycles per sec. from all channels, with some occasional slower activity, 3–4 cycles per sec. of increased amplitude.

Intelligence quotient (Dr. Flora Macdonald) 81.

Treatment and Progress.—The patient is now (November, 1952) having thyroid gr. 1 thrice daily. He has grown 3 in. in a year, and there is considerable quickening of activity, intelligence, and body warmth. His blood cholesterol level is now 146 mg. per 100 ml. and his bone age 11 years.

For the radioactive iodine studies see below.

P. K.—*Female, aged* $8^1/_2$ years. Thyroid therapy was started at the age of 1 year. She continued to take no more than gr. $^1/_2$ daily. She has a family reputation for quick-wittedness.

When examined on Nov. 17, 1951, her height was 40 in. (average for a girl of her age 51 in.). Her height was that of a girl aged $4^1/_2$ years, and her retardation was more than 20%. The ratio of upper segment to lower segment was 1.1 : 1. Weight 43 lb.—i.e., 20 lb. below average for girls of her age. The abdomen was protuberant and there was a small umbilical hernia. The skin was dry. The extremities were cold but there was no cyanosis. There was an increase of hair growth on the extensor surfaces of the arms. The thyroid gland was soft but enlarged in both lobes, palpably but not visibly.

Blood cholesterol 284 mg. per 100 ml.

Blood count.—Red cells 3,200,000 per c.mm. Hb 72%.

Radiography of Carpus.—Hamate and capitate only had appeared. Bone age 2–3 years.

Electrocardiograms within normal limits.

Electro encephalogram (Dr. F. Graham Lescher) within normal limits.

Intelligence quotient (Dr. Flora Macdonald) 73.

Treatment and Progress.—Her height has increased by $4^1/_4$ in. in a year (November, 1952). Her bone age is now 4 or 5 years. Her thyroid is no longer palpable. She is having thyroid gr. $^1/_2$ thrice daily—a larger dose gives her a headache and makes her fretful. The blood cholesterol is 125 mg. per 100 ml.

J. K.—Female, aged $6^1/_2$ years. Thyroid therapy was started at the age of 1 year.

When examined on Nov. 17, 1951, her height was 37.5 in.—8 in. (17%) below average. The ratio of upper to lower segment was 1.2 : 1 (average at $4^1/_2$ years). Her lips were pink and her extremities cold. The abdomen was not so protuberant as that of P. K., and there was no umbilical hernia. The skin was dry, and the extensor surfaces of the arms were hairy. There was a small soft enlargement of both lobes of the thyroid.

Blood cholesterol 239 mg. per 100 ml.

Blood count.—Red cells 3,900,000 per c.mm.; Hb 85%.

Radiography of Carpus.—Hamate and capitate only had appeared. Bone age 2–3 years.

Electrocardiograms within normal limits.

Electro encephalogram (Dr. F. Graham Lescher) abnormal. There was much slow activity, of raised amplitude and from all channels. The rate was 3–6 cycles per sec.

Intelligence quotient (Dr. Flora Macdonald) 69.

Treatment and Progress.—She is having thyroid gr. $^1/_2$ thrice daily (November, 1952). She has grown $4^1/_4$ in. in a year, the thyroid gland is not now palpable, and the blood cholesterol is 140 mg. per 100 ml.

DIAGNOSTIC STUDIES

G. W. K.—The thyroid gland was removed on Jan. 22, 1952. Dr. G. R. Osborn reported on its histology as follows (see fig. 3):

> "Microscopically the normal lobular pattern is present except in the nodules; it is obscured by the degenerations which are present, however. The acini present vary greatly in size, though many are within normal limits. Very few contain any colloid; when present it is polychromasic and dense. The acinar cells are mostly flattened or cuboidal, the shape is mainly affected by the extraordinary degree of nuclear variation which is present. Many nuclei are upwards of 4–6 times normal size; they are hyperchromatic and not unlike those seen at the height of thiouracil action. There is some fibrous replacement of acini; much of this is slight, but some is extensive. Large numbers of cysts about the size of a pin's head appear to be the result of distension of acini with serous fluid; very few of these contain colloid. The nodules which are present appear to have arisen in the usual way, but they show nuclear variation of lesser degree and much larger serous cysts. Lymphocytic infiltration is inconspicuous. Arteriosclerosis is present, but early."

The histological appearances of this thyroid gland do not greatly differ from the degenerate areas in the much larger glands removed from the goitrous cretins described by Stanbury and Hedge (1950), who regarded the

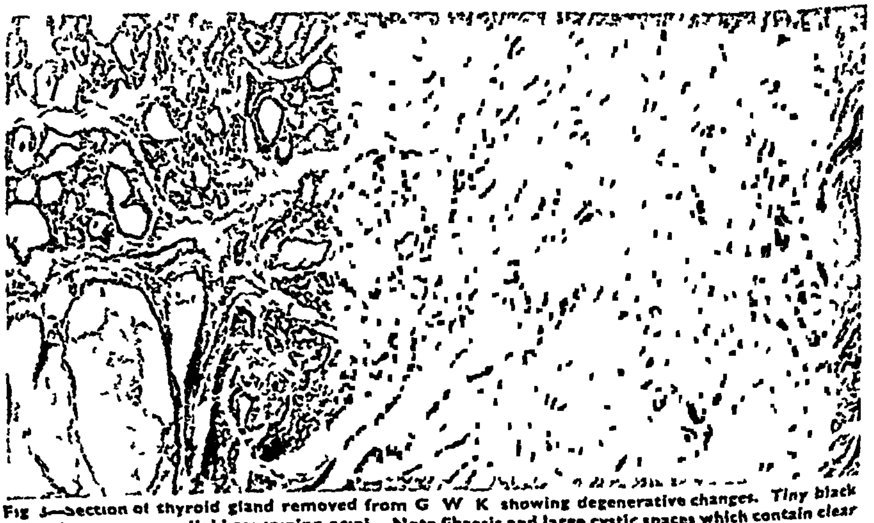

Fig. 3—Section of thyroid gland removed from G. W. K. showing degenerative changes. Tiny black circular areas are colloid-containing acini. Note fibrosis and large cystic spaces which contain clear serous fluid but no colloid. (×90.)

giving full indications of the difficulties likely to be encountered, of the precautions needed, and of the type of apparatus (e.g., pipettes) to be used.

In discussing these problems a statistical approach is essential. Replicate determinations and comparisons between different laboratories yield answers whose random variation is commonly greater than many pathologists are willing to admit.

The suggestion, in your leading article, of a review of these problems is timely and valuable. It is to be hoped that the Association of Clinical Pathologists, in collaboration with the other bodies you mention, will undertake the task.

Sheffield. ARTHUR JORDAN.

MEPHENESIN IN RHEUMATISM

SIR,—The considerable number of reports recently published regarding the toxicity of phenylbutazone ('Butazolidin'), and the very wide use of this drug in various skeletal complaints unconnected with rheumatoid arthritis, prompt the following comments on the results achieved with another agent, mephenesin. I used this in between 20 and 30 cases of "rheumatic" complaints, which included periarthritis and various forms of "fibrositis" with and without neuritic involvement.

The drug was supplied in 0·5 g. tablets as 'Tolserol' by E. R. Squibb & Sons.

A woman of 70, suffering from chronic fibrositis, refused to continue to take the tablets "because they were too big," and was excluded from this group.

All the remaining patients improved considerably within a short period, and the following examples illustrate typical results:

A man, aged 46, suffering from acute spasm at the sacro-iliac junction, reported much benefit within three to four days and complete relief after one week.

A man, aged 50, with acute lumbago and sciatica-like pain in the right leg, was free from symptoms after one week's treatment.

A housewife, aged 32, who had suffered from chronic low backache for six or seven years, with exacerbation following the birth of a child two years ago, had complete remission within two days.

A woman, aged about 50, with chronic fibrositis, mainly of the trapezius, and some low back pain of five years' standing, was able to look over both shoulders after four days' treatment, although she had been unable to do this for about five years.

A woman, aged 40, with anxiety neurosis and chronic fibrositis of the shoulder, was much relieved within four days. Greater improvement resulted when treatment with methylphenobarbitone was combined with mephenesin, though the barbiturate caused some feeling of lassitude.

A woman, aged 40, with a history of sciatica following a divorce five years ago, had a second attack thought to be due to a domestic disturbance in August, 1952. She had been admitted to hospital where a prolapsed intervertebral disc was diagnosed, although not shown by X-ray examination. She had sciatica of the right leg and severe sacro-iliac spasm but no clinical evidence of prolapsed disc. After four days' mephenesin, she was able to walk naturally, but full therapeutic response necessitated the administration of 6 g. daily for sixteen days.

The optimum daily dose was usually 4—6 g., given in divided doses every four hours, except during the night. Most patients responded satisfactorily within from two to seven days, and in severe chronic cases, where there may be a tendency for the symptoms to recur, it would probably be advisable to give periodic short courses as necessary, rather than to prolong treatment in the hope of permanently eradicating the disease. 2 patients had very slight vertigo, but no other toxic effects were encountered, in the cases treated with tolserol.

Mephenesin is a muscle relaxant and its blocking action breaks the spasm-pain cycle, but the drug does not appear to have any direct analgesic effect; but in my series it was not necessary to use any other drug to relieve pain, for the response to mephenesin was rapid. When this drug is used in the treatment of patients with neuroses, a suitable barbiturate can be given at the same time. But 2 patients with anxiety neurosis and definite hypertension became decidedly worse when mephenesin was *substituted* for barbiturates in the treatment of their neuroses.

In general, acute cases respond more rapidly than chronic conditions; but mephenesin appears to be very effective in a variety of fibrositic disorders, and its virtual freedom from toxicity by the oral route makes it suitable for routine use.

Worthing, Sussex. J. R. B. PECKOVER.

CIRCUMCISION OF THE NEWBORN

SIR,—The question raised by Dr. Morris (May 2) concerning bleeding from hæmorrhagic disease of the newborn following immediate circumcision—and indeed hæmorrhage due to other causes after this operation—is answered by the work of Miller and Snyder.[1] They advocate operation only upon normal, healthy, full-term infants. In their series no babies with icterus, erythroblastosis, or purpura were circumcised: the rhesus state of the mother had previously been determined; and they were able to show, from a study of 700 bleeding and coagulation times taken after delivery, that there was no inherent defect of the clotting mechanism at birth. Postoperative bleeding was of import in 0·3% of the children and was due to faulty technique.

Dr. Morris's suggestion that circumcision was delayed until the eighth day of life because of the dangers of bleeding finds confirmation in the writings of Maimonides[2] and also in the *Talmud*.[3] But hæmorrhage itself would have been no deterrent to the ritual, rather the reverse, for the shedding of blood was of significance [4] and was often all that was demanded.

The age at which circumcision is done varies so much throughout the world and is so connected with the origins of the act that (even excluding savage races and manhood-initiation ages) no one reason can be given. Among the Jews the eighth day was chosen, for in the first week of life neither animal nor man could be offered to God.[5] [6] In people of other sects or cultures, circumcision might be at the end of the seventh day of life, as in the Falashas, in the first month among the South-western Arabs, in the second month among the Mazequas, in the third year among the Persian Mohammedans, or in the seventh year among the Christian Copts.[7] The Arabs circumcised when the child was 13, for at that age Ishmael was thus operated upon. Some Islamite tribes performed the rite when the child was old enough to be able to quote religious tracts or profess his faith, and others when the boy was at an age (variously and curiously defined) of reason.

Public Health

Smallpox

No further cases have been reported from Lancashire and the West Riding where the outbreak of smallpox has so far involved 30 people, 8 of whom have died. A fortnight has now gone by without a new case. At the Chesterfield Royal Hospital, Derbyshire, precautions have been taken pending the result of investigations into the death of a 19-year-old youth on May 24.[8]

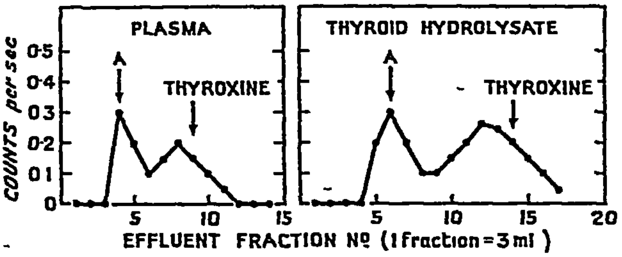

Fig 4—Result of iodine fractionation in plasma and thyroid gland of G W K by Mrs Pitt Rivers and Dr Jack Gross. Fraction A is an artefact of the process. No quantitative estimation of thyroxine was made and amounts of thyroxine in plasma and in gland are not comparable, because aliquots were used.

changes as the sequel to compensatory hyperplasia. The steady enlargement of the gland when thyroid administration was stopped in the six months before coming to hospital supports this theory. Twenty-four hours before the gland was removed, a dose of 107 µC of radioactive iodine (I^{131}) was given, and the gland, together with blood taken at the time of the operation, was sent to Mrs Pitt-Rivers and Dr Jack Gross at the National Institute for Medical Research. They reported as follows:

"The thyroid was hydrolysed in 2 *N* sodium hydroxide by refluxing for 17 hours. It was then brought to pH 1–2 and extracted with butanol. The butanol extract was concentrated to a very low volume and put on the kieselguhr column. The plasma was acidified and extracted with butanol, and the butanol extracts were evaporated (Gross and Pitt Rivers 1951, 1952) and put on the kieselguhr NaOH column.

UPTAKE AND URINARY EXCRETION OF RADIOACTIVE IODINE IN CASE G K

Date	Time to half-peaks (min.)	4 hr	12 hr	24 hr	48 hr	72 hr
			Gland content			
*Jan. 1, 1952 (fig 5)	90	48%	60%	59%	54%	52%
†Oct. 28, 1952 (fig 6)	70	52%	61%	57%	49%‡	40%‡
			Urinary excretion			
Jan 1, 1952				12.7%	15.1%	
Oct 28, 1952				17.4%	23.2%	29.7%

All percentages are of total dose.
*Dose 26.3 µC of I^{131}.
†Dose 21.2 µC of I^{131}.
‡Following administration of thiocyanate 2 g at 26 hr.

Thyroxine was identified in the radioactivity in both extracts (fig 4). Fraction A of radioactivity is an artefact of this process. The amount of thyroxine present was not estimated."

G K was investigated by radioactive-iodine techniques in Prof E J Wayne's department in Sheffield in January and October, 1952. Dr H Miller, Dr A G Macgregor, and Dr R S Weetch conducted the investigations. The first investigations were made when thyroid therapy had been stopped for more than three weeks, and before the second series all thyroid medication had ceased for twenty-four days. The results are shown in the accompanying table.

The peak uptake in both tracer tests was about 60%. The thyroid clearance rate, on the first occasion, was 75 ml per minute at one hour, and on the second occasion 76 ml per minute at one and-a-half hours. The plasma activity forty-eight hours after the tracer dose on Jan 1, 1952, was 0.91% per litre, and of this 0.64% per litre was in the protein-bound fraction. Thus 70% of the iodine fraction was in the protein-bound form. On the second occasion the patient was given potassium thiocyanate 2 g at twenty-six hours. At this time his plasma activity was 0.59% per litre, and the protein-bound iodine was 0.40% per litre, giving 68% of the radioactivity in a protein-bound form.

Potassium thiocyanate is a goitrogenic substance and discharges from the gland any radioactive iodine which is not linked to protein (Vanderlaan and Vanderlaan 1947). The result is shown in fig 6, which shows that there was only a small reduction of gland activity immediately after the dose of thiocyanate, but Dr Miller observes that "this appears to be a genuine effect and probably represents a small fraction of I^{131} in inorganic form turned out into the blood and later reabsorbed to some extent." The curve should be compared with the curve of gland activity obtained in January (fig 5), and on this difference Dr Miller comments: "The biological elimination following thiocyanate administration appears to be significantly quicker than that observed in the first test. This could be explained if the thiocyanate did have some interference on the rate of reabsorption of I^{131} from the blood to the gland."

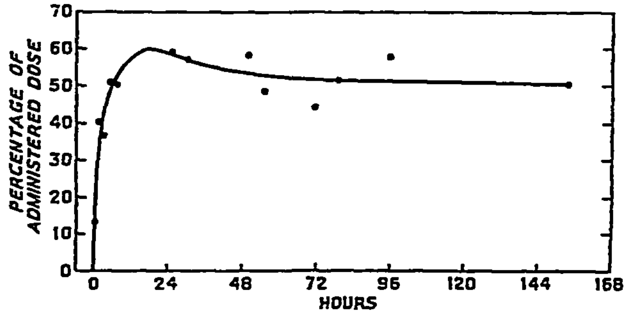

Fig 5—Gland content of I^{131} in G K. in January, 1952, after a dose of 26.3 µC. Rapid uptake of iodine falls within hyperthyroid range.

DISCUSSION

It has been shown that the thyroid gland of the eldest child of this family of four cretins can both synthesise thyroxine and liberate it into the plasma. Studies with I^{131} in the second child have shown that his gland can synthesise protein-bound iodine and liberate it into the plasma. Moreover, the activity of his gland is such that, whether judged by the time of the half-peak uptake, the twenty-four-hour urinary excretion, the clearance-rate, the total gland activity or the protein-bound plasma activity, these radioactive-iodine tests taken alone indicate hyperthyroidism in him (Goodwin et al 1951). Nevertheless the indisputable clinical evidence is that these children have hypothyroidism. These results confirm the reports by Lerman et al (1946),

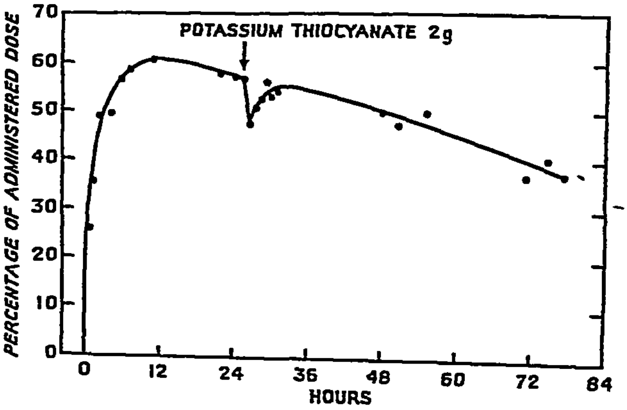

Fig 6—Radioactive-iodine uptake and discharge in G K. in October 1952. At 26 hr thiocyanate 2 g was given, and increased rate of fall compared with fig 5 may be attributed to interference with rate of reabsorption of I^{131} from blood to gland. Note that this curve is quite different from that obtained by Stanbury and Hedge (fig 7).

Notes and News

THE ROYAL SOCIETY

At the society's conversazione on May 21, the National Institute for Medical Research and the M.R.C. Blood Transfusion Research Unit from the Postgraduate Medical School of London set out some of the results of their work on the preservation of living cells in the frozen state. In the deep-freeze, red cells can be stored for months at − 79°C. Many technical difficulties have been overcome, but a few remain to be solved before the full promise of the method in blood-transfusion work is fulfilled; a rather lower temperature may prove best in the end. Moreover, there is still much to learn about what happens to the red cell under various conditions of storage. In the past it has been hard to store for more than a few days bull spermatozoa for artificial insemination in breeding experiments; but semen, deep-frozen in glycerol, has been stored for up to a year and used successfully.

Archæologists applauded and forgers fled before Mr. E. T. Hall's X-ray spectrometer from the Clarendon Laboratory; for this beautiful machine will identify in a moment or two the metals in a Roman brooch or a doubtful coin. The specimen is irradiated and, as the crystal of the spectrometer turns, the peaks of characteristic radiation in the secondary beam are picked out; and the critical wave-lengths of these peaks identify the element responsible. Of course, this method of analysis is not new, but the deftness of control and the rapidity with which this spectrometer records the results and counts the constituents of the secondary beam are impressive additions to the technique. As well as protecting the archæologist's treasures from cruder analysis and dismaying the counterfeiter, it may prove useful in industries where a quick answer is needed—for example, when the composition of a melt must be known within a few minutes.

The rare metal, germanium, has an odd and, as far as is known, unique property: when an electric current is passed through a germanium crystal under suitable conditions the transparency of the crystal to infra-red light changes. The current, it seems, increases the density of free electrons in the crystal, and more electrons mean more absorption in the infra-red part of the spectrum. This effect was very neatly demonstrated by Dr. A. F. Gibson and Mr. R. Lawrence, of the Telecommunications Research Establishment at Great Malvern. The current through the crystal came from a gramophone, and a tungsten lamp shone an infra-red beam through it too, so that the intensity of the emerging beam varied in response to the changes in the current from the gramophone. Thus, the sounds of the orchestra on the record were transformed into an infra-red beam of varying intensity, which was in effect a radio beam of extremely short wavelength. The infra-red music then disappeared into a photoelectric cell connected to a loudspeaker. And so the orchestra emerged. As the demonstrators modestly observed, the quality of their infra-red radio link was about the same as that of the B.B.C.

Mr. L. R. O. Storey, of the Cavendish Laboratory, also had a gramophone. He played a record of some alarming atmospherics—just like those exasperating noises that crackle and whine out of some loudspeakers as the announcer is reading the latest Test score. Lightning flashes are to blame for the brittle clicks, which are local phenomena; but the more melodious "whistlers" may reach the receiver by a roundabout path from a very long way off. The waves from a local click set off in a giant arc along the Earth's magnetic lines of force, pass over the Equator about 7000 miles up, and come to earth in the opposite hemisphere. During their journey through the ionosphere, the waves of high frequency travel faster than their companions of low frequency, so they arrive a few seconds earlier. What started off as a click, therefore, comes out of the receiver as a long falling note of astonishment. And the whistler may bounce to and fro along the lines of force, producing a series of strains with a dying fall on both sides of the Equator, just as though Nature were whistling incredulously at the success of her prank as she withdraws to prepare another programme in the ionosphere. The properties of these atmospherics have shown, among other things, that the Earth's atmosphere extends to a much greater height than we imagined.

Bees lead well-ordered lives, and Mr. C. R. Ribbands, of the Rothamsted Experimental Station, explained some of their social and domestic arrangements. He showed how the life of the bee community has evolved by simple stages to its present complexity. All the available food is shared among the community, and this unselfish distribution means, for one thing, that all the bees smell to each other of the same flowers, so that unlucky bees can seek out the scent of likely crops and the colony can forage as a unit.

There were plenty of animals about, and the Marine Biological Association of the United Kingdom brought along a mixed bag of sea creatures. The starfishes and brittle-stars are attractive enough, but they are unpopular for their interference with man's pleasures. The starfish likes oysters and mussels, and the lethargic brittle-star takes up a lot of bedspace that would otherwise be a feeding-ground for more appetising fare.

The most disconcerting exhibit was undoubtedly the one demonstrating the effect of an echo on a speaker. Dr. E. C. Cherry and Mr. A. J. Fourcin, of the Imperial College of Science and Technology, put the nimblest speaker out of his stride by returning his own words to him through headphones $^1/_5$ second after they had been uttered. Normally he hears his words almost as soon as he speaks, and, if he is wise, his thoughts run slightly ahead of his words. The delicate speech mechanism has been built up under these conditions, and if he is reminded in this way of what his past experience has conditioned him to forget, everything may go awry. The effect in this experiment was certainly devastating: commentaries that ran confidently for a few seconds were cut short by hesitancy or complete silence, and sometimes by unintelligible stammering or slurring. Clearly the device would have its uses in curbing the less engaging after-dinner speakers.

WORLD HEALTH ASSEMBLY

The sixth World Health Assembly, which is meeting in Geneva, is to consider a recommendation that the production of heroin be abolished throughout the world. The proposal has been put before the assembly by the committee on programme and budget, and, if approved, it will be passed to the Economic and Social Council of the United Nations and its commission on narcotics. The abolition of legally produced heroin would do much to facilitate the control of its illegal use. The committee also asked for a study of the steps necessary to launch a campaign against smallpox. Governments and regional committees of W.H.O. will be asked about their views before the executive board begins its study, the results of which will be presented to next year's assembly.

MINISTRY OF PENSIONS HOSPITALS

Three months ago the Prime Minister announced that the Ministry of Pensions would be amalgamated with the Ministry of National Insurance to form a new Ministry of Pensions and National Insurance, and that the medical treatment it has undertaken—including the management of hospitals and the supply of artificial limbs, surgical appliances, and invalid vehicles—would be transferred to the Ministry of Health and the Department of Health for Scotland.

Since the National Health Service was set up in 1948, war pensioners, like other members of the community, have been entitled to the care of practitioner and hospital without charge, and have had less need of separate care: indeed, of some 35,600 war pensioners receiving inpatient treatment in the year ended in March, only 14,200 had it in Ministry of Pensions hospitals compared with 21,400 in N.H.S. hospitals, including sanatoria and mental hospitals. The Ministry of Pensions hospital service has accordingly contracted; four hospitals, with a total of about 1600 beds, have been transferred to the N.H.S.; and in the eight hospitals which, with certain units elsewhere, the Ministry of Pensions has retained, about 3000 N.H.S. patients have been treated during the past year. Even so it has been difficult to keep these eight hospitals full, and it is hoped that their closer integration with the N.H.S. will increase the occupancy of their beds.

A white-paper[1] sets out the proposed transfer of functions. The hospitals now to be transferred to the health departments are: Queen Mary's, Roehampton; Chapel Allerton, Leeds; Mossley Hill, Liverpool; Dunston Hill, Gateshead; Rookwood, Cardiff; Mount Pleasant, Chepstow; Edenhall, Edinburgh; and Leopardstown Park, Dublin. In England and Wales the hospital staffs and the headquarters staffs engaged in hospital administration will be transferred to the Ministry of Health, and in the first instance the hospitals will be directly administered by that department, though it is

Stanbury and Hedge (1950), and McGirr and Hutchison (1953) that children with familial goitrous cretinism have very active thyroid function

When the chemical results of this thyroid overactivity are considered, a very different picture emerges The three cretinous siblings described by Stanbury and Hedge (1950) could extract iodide from the blood, but, when thiocyanate was administered at four hours, 70–90% of the radioactive iodine was discharged into the blood two hours later, indicating that nearly the whole of the iodine had not by this time become organically bound (fig 7) The nine familial goitrous cretins described by McGirr and Hutchison (1953) could bind iodine to protein, and six of them were proved to be capable of releasing the organically *bound iodine into the blood* These workers concluded that part of the protein-bound fraction in two of their cases might be diiodotyrosine, and in the plasma of a third patient Mrs Pitt-Rivers and Dr Gross excluded the presence of thyroxine and triiodothyronine In one of the four children reported here the same workers identified thyroxine in both the gland and the plasma, though they could not estimate its amount

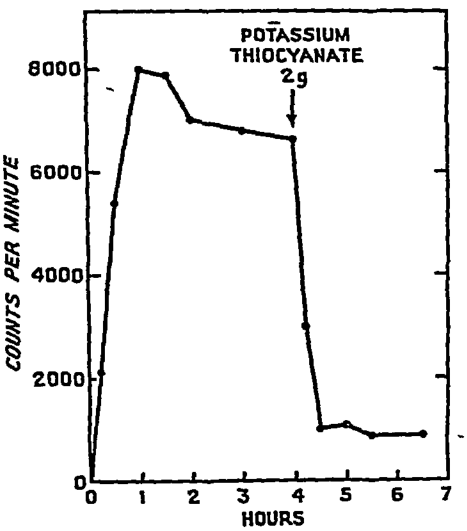

Fig 7—Curve from Stanbury and Hedge (1950), in counts per minute and not in percentage of administered dose, shows immediate fall in gland content of radioactive iodine which occurs in goitrous cretinism when little iodine has become protein bound

Clinicians will be grateful for any help which can be obtained from radioactive iodine studies in doubtful cases of thyroid overactivity or underactivity It is apparent from these results that the diagnosis of hypothyroidism and cretinism must remain predominantly a clinical problem All who have studied the records will agree that these familial goitrous cretins had hypothyroidism, and they responded normally to the administration of thyroid There was in them no peripheral resistance to the utilisation of thyroid

In none of the published cases, except G W K, has thyroxine been identified, but in none of the published cases, except case 5 of McGirr and Hutchison (1953) and then only in the plasma, has it been proved to be entirely absent Hamilton et al (1943), in their pioneer radioactive iodine studies of hypothyroidism in children, investigated two severely hypothyroid children with goitres and discovered thyroxine in the removed glands It may eventually be shown that the thyroid glands of all these goitrous cretins, whether familial or not have at one time been capable of making thyroxine, but in inadequate amounts It is obvious from the published cases that the degree of cretinism varies being severe in the cases of Stanbury and Hedge (1950) and no more than moderate in mine The full clinical account of the cases reported by McGirr and Hutchison (1953) will be awaited with interest, but from the details of height age and bone age already given, it appears that in their cases too the degree and the time of onset of hypothyroidism varied greatly

From the histological appearances of the thyroid gland removed from G W K it can be assumed that the production of thyroxine would be progressively impaired, and that the clinical picture of hypothyroidism would develop gradually This agrees with the observation of de Quervain (1924) that the retardation in endemic cretinism is slower in the patients with goitres than in those with atrophic thyroid glands It is usual to attribute the late diagnosis of cretinism to parental negligence or to medical ineptitude This concept of a progressive and relative hypothyroidism in goitrous cretinism permits a more charitable opinion In G W K the diagnosis was made at the age of 8 years, and in G K at the age of 4 years, and in P K and J K not until the age of 1 year, despite the previous recognition of hypothyroidism in the older children In the two brothers described by Lerman et al (1946) symptoms were first noticed at the ages of 10 years and 5 years Thyroid therapy was given intermittently and, as in the family described here, when thyroid therapy was stopped the thyroid gland enlarged Reduction in the size of the gland when adequate thyroid therapy was instituted was observed in the K children, but such an observation could obviously not be expected in cases where the gland was large and degenerate In the cases described by Stanbury and Hedge (1950) cretinism was diagnosed in infancy and thyroid therapy was started then Enlargement of the gland was not observed until the ages of 7 and 13 years in their two cases in which this fact was reported These facts make probable the hypothesis that the gland does not enlarge unless the circulating thyroxine, whether produced in the body or administered, is insufficient to depress the secretion of the thyrotropic hormone An enlarging thyroid gland indicates that the dose of administered thyroid is inadequate It may be assumed that the deficiency in the synthesis of thyroxine in these cases occurs at different stages, either in the binding of iodine to protein—inability to form the "diiodotyrosine like" fraction of Chaikoff and Taurog (1949)—or in the conversion of diiodotyrosine to thyroxine (Harington 1926, Harington and Barger 1927) or to triiodothyronine (Gross and Pitt Rivers 1952)

CONCLUSIONS AND SUMMARY

A family of four hypothyroid siblings is described In the eldest child, in whom thyroid therapy had been stopped for six months, a moderate sized goitre developed In the younger children, in whom thyroid therapy had been inadequate, small soft enlargements of the thyroid gland were present which disappeared when adequate therapy was instituted

Thyroxine was present both in the plasma and in the removed thyroid gland of the eldest child In the second child considerable thyroid activity was proved by radioactive-iodine studies This dissociation between the clinical diagnosis (hypothyroidism) and the radioactive iodine diagnosis (hyperthyroidism) has been noted by other workers

In these children it is assumed that the amount of thyroxine formed must be inadequate for their needs It is suggested that the clinical records of goitrous cretinism, both endemic and sporadic, often denote a relative and progressive, rather than an absolute, insufficiency of thyroxine The enlargement of the gland is an index of the degree of thyroxine inadequacy

The stage at which these chemical defects in thyroxine formation occur obviously varies in the published cases of goitrous cretinism In some, as in the cases described here, the deficiency may be quantitative and not qualitative

Dr P Hay Heddle rescued these children from their hypothyroid state I am grateful to Sir Charles Harington, F R S Mrs Pitt Rivers, and Dr Jack Gross for their chromatographic studies, and to Prof E J Wayne, Dr H Miller, Dr A G Macgregor, and Dr R S Weetch for their radio

intended that "as and when appropriate" they shall be entrusted to regional hospital boards and management committees. When this is done, war pensioners will still have first call on the services of these hospitals, and, so long as a hospital is substantially used for war pensioners, the management committee will be specially constituted. Administration of the Scottish hospital will be entrusted from the outset to the appropriate regional board and board of management. The Roehampton Hospital, with its international reputation for the treatment of certain disabilities, and its own board of governors, will require special arrangements if and when it is brought within the N.H.S.

ACCIDENTS AT HOME

"SAFE at home," like "safe in bed," is one of those common sayings which do not stand up to examination. We think the total of those who die from accidents on the roads—about 48,000 yearly—sufficiently appalling, but those who die from accidents in the home easily outnumber them: the average during the years 1940–49 was 60,000 yearly. These figures appear in a new Home Office report,[1] from the Standing Interdepartmental Committee on Accidents in the Home; they refer only to fatal accidents because no accurate assessment is available of non-fatal accidents. More than a quarter of those who die are under 15 and more than half over 65; and more children under 15 die from home accidents than from any single infectious disease. The commonest accidents are falls, accounting for 58% of the total, burns and scalds causing 13%, suffocation 12%, and coal-gas poisoning 8%. About nine-tenths of the falls happen to old people, and so do over half the burns and scalds and nearly two-thirds of the coal-gas poisonings. Nearly all the suffocations are of babies sleeping on down pillows.

Surveys have shown that faulty design of equipment is responsible for less than 10% of domestic accidents; some 20% were due to poor maintenance, particularly of flooring, stair-treads, and hand-rails, and to bad lighting. But most of the accidents happened in the course of ordinary domestic jobs, particularly at busy times: more than half happened in the kitchen or living-room while cooking or washing was being done, or tea being made. Fireguards were shockingly scarce: in over 1000 houses where a coal fire was burning, a fireguard was in use in only just a third of those containing children under 6; and only 7% of households containing old people over 70 used guards. "It is hardly surprising," the report notes, "that so many children and old people are killed, crippled, and disfigured from burns each year."

Legislation already does something to enforce the use of guards. The Children and Young Persons Act, 1933, has a provision aimed at preventing people in charge of children under 7 from allowing such children to be in a room with an inadequately protected fire; and the age has now been raised to 12, and the wording changed to cover "any heating appliance liable to cause injury to a person by contact therewith." Guards have also been made compulsory on prescribed kinds of gas and electric fires and oil heaters sold to the public. People are also getting some teaching on the prevention of fires by the fire prevention officers who arrange exhibitions and demonstrations, give talks, and show films. The British Standards Institution are doing their part by laying down principles of good workmanship and safe design for domestic gear, and these have been adopted by reputable manufacturers. But the final responsibility for preventing accidents must always lie with individuals, and in an appendix the committee list some common causes of accidents which all of us should have in mind. These include a dustpan and brush left on an ill-lighted staircase, a loop of flex across a living-room floor (which may give a shock or prove a trip-wire), a loose mat on a slippery floor, loose stair carpets, unguarded bedroom fires, a saucepan handle sticking out beyond a stove where a child can reach it, a loose table-cloth which a child can tug, an electric fire or radio in the bathroom, medicines or garden chemicals left within reach of a child, and down pillows for babies. The committee add some precautions for those leaving the house. See that your cigarette is out, the electric iron unplugged, the gas-taps turned off, fires guarded, and television and wireless disconnected.

Empire Rheumatism Council

Sir Henry Cohen will deliver a Coronation lecture at 1, Wimpole Street, London, W.1, on Thursday, July 2, at 8.15 P.M. He will speak on the Concept of Collagen Disease.

University of London

The governing body of the British Postgraduate Medical Federation has approved the award of postgraduate travelling fellowships for 1953–54, tenable for one year, to the following:

M. B. McIlroy, M.R.C.P., of St. Bartholomew's Hospital (respiratory function, U.S.A.).

D. Marrack, M.D., of the Postgraduate Medical School of London (biochemistry, U.S.A.).

T. A. J. Prankerd, M.R.C.P., of University College Hospital (hæmatology, U.S.A.).

P. Story, M.D., of St. Bartholomew's Hospital (hæmatology, U.S.A.).

University of Leeds

On June 25, on the occasion of the meeting of the British Association of Urological Surgeons in Leeds, the honorary degree of D.SC. will be conferred on Prof. Charles Huggins (Chicago) and Mr. R. Ogier Ward.

Dr. H. N. Green has been appointed professor of experimental pathology and director of cancer research.

Professor Green graduated as M.B. at the University of Sheffield in 1924. In 1925 he obtained the degree of B.SC., with first-class honours, and a year later took the degree of M.SC. He became M.D. in 1927. From 1926 to 1933 he worked in Sheffield as clinical assistant to Sir Edward Mellanby at the Royal Infirmary and as research assistant in the university department of pharmacology. In 1933 he was appointed lecturer in pathology at the University of Cambridge where he remained until 1935, when he returned to the University of Sheffield as professor of pathology. Alongside his professorial duties he has directed cancer research in the university. He has also directed a Medical Research Council team which has investigated the nature and mechanism of shock; and from 1944 to 1945 he held the rank of lieut.-colonel in the British Traumatic Shock Unit II of the R.A.M.C. and served abroad in North-west Europe. His publications include *Biological Actions of the Adenine Nucleotides* which appeared in 1950.

Major C. K. Anderson has been appointed research fellow in genito-urinary pathology, and Dr. P. G. Keates research fellow in radiodiagnosis.

University of Birmingham

The following appointments are announced: Dr. J. H. Cort and Dr. K. White, lecturers in physiology; Dr. Constance Ross, research fellow in the departments of pædiatrics and child health and of pharmacology.

The title of honorary part-time lecturer in medicine has been conferred upon Dr. O. L. Wade, senior registrar in the medical professorial unit, United Birmingham Hospitals, during the tenure of his present appointment. The title of university research fellow, for the duration of their present appointments, has been conferred upon the following: Dr. H. Bickel, Dr. J. D. Blainey, Dr. J. P. Bull, Dr. D. S. Rowe, and Dr. I. D. Singh.

Mr. Stanley Way will give the Ingleby lectures for 1953 on Thursday and Friday, June 18 and 19, at the Medical School at 4 P.M. He is to speak on the Ætiology of Carcinoma of the Body of the Uterus.

Queen's University, Belfast

At the summer graduation the honorary degree of LL.D. will be conferred on Dame Hilda Lloyd.

Royal College of Physicians of Edinburgh

The college has approved of regulations permitting suitably qualified persons to read in, and borrow from, the library. The college library, the use of which has hitherto been restricted to fellows, was founded in 1681 and is the oldest medical library in Scotland. It is almost entirely restricted to medicine and contains nearly 200,000 volumes.

Royal College of Surgeons of Edinburgh

At a meeting of the college held on May 20, with Prof. Walter Mercer, the president, in the chair, the following were admitted to the fellowship:

A. J. C. Allison, A. E. Amoils, Ebenezer Sunderaraj Chellappa, A. F. G. C. Christie, D. C. Cooke, E. C. Edwards, J. C. Foster, J. D. Fraser, D. R. Gunn, I. A. Harris, H. H. Martin, Jit Shrimukh Mehta, M. N. Menzies, Lumir Louis Ptak, Kazimierz Rubinstein, Upendra Narain Shahi, Mohammed Raza Shirazi, J. D. C. Sim, I. M. Stewart, Gulabbhai Gopalji Vashi, R. D. Venn, W. F. Walker, Ian Wilson.

Woodberry Down Health Centre

A joint committee of the London Executive Council and the London Local Medical Committee have selected six general practitioners to work at this health centre.

Royal Medical Benevolent Fund

The annual general meeting of the fund will be held at 11, Chandos Street, London, W.1, on Tuesday, June 9, at 5 P.M., with Lord Webb-Johnson, the president, in the chair.

RADIOACTIVE-IODINE STUDIES IN NON-ENDEMIC GOITROUS CRETINISM

E M McGirr
M.B Glasg, M R C P, F R F P S
UNIVERSITY LECTURER IN MEDICINE, MUIRHEAD DEPARTMENT OF MEDICINE, ROYAL INFIRMARY, GLASGOW

VISITING PHYSICIAN, ROYAL HOSPITAL FOR SICK CHILDREN, GLASGOW

Radioactive iodine has become widely used in the study of thyroid disorders since the original investigations with I^{128} (half life 25 minutes) were made by Hertz et al (1938), and with I^{131} (half-life 8 days) by Hamilton and Soley (1939) Goodwin et al (1951) discussed the relative merits of the various methods and reached the conclusion, supported by their own experience, that the amount of protein-bound iodine in the plasma 48 hours after the administration of radioactive iodine gives more valuable information about thyroid function than does either the uptake of iodine by the thyroid gland or its excretion by the kidneys

High values for the thyroid uptake of radio iodine have been observed not only in thyrotoxicosis but also in other thyroid disorders They have been found in non-toxic goitre of recent development (Raben and Astwood 1949) and in cretins with non-endemic goitre (Hamilton et al 1943, Lerman et al 1946, Stanbury and Hedge 1950, Stanbury 1951) They have been produced experimentally by deprivation of iodine, by blocking the utilisation of iodine with anti-thyroid drugs (Raben and Astwood 1949), and by the injection of thyrotropin (Stanley and Astwood 1949)

Abnormally large amounts of protein-bound I^{131} are found in the plasma characteristically in thyrotoxicosis, and occasionally persist in successfully treated thyrotoxic patients who no longer show any clinical evidence of hyperthyroidism (Blomfield et al 1951) Abnormally large amounts of non-radioactive iodine I^{127} have also been found in similar cases (Engstrom et al 1950, Man et al 1951) and in a patient with a simple goitre (Man et al 1951)

We have found abnormally large amounts of protein-bound I^{131} in the plasma of patients with non-endemic goitrous cretinism, who are of particular clinical interest because they presented with the unusual combination of hypothyroidism and thyroid enlargement unrelated to iodine deficiency or to the action of any known goitrogen

MATERIAL

The ages of the 12 patients ranged from 2 years and 9 months to 20 years, 5 were males and 7 females, 4 were members of one family, and 3 were closely related to them, 2 were members of another family, and 3 were unrelated to either family or to each other The patients, each of whom had an enlarged thyroid gland, presented the typical features of hypothyroidism These cases are summarised in table I The ages of onset of recognisable symptoms were sometimes difficult to determine but varied from a few months to 3 years Since the distinction between cretinism and juvenile myxœdema appears artificial in these cases, most of which occurred in the one family group, and for the sake of brevity, the patients are classified as cretins None of the patients came from an area of endemic goitre, and in none was there a history of deprivation of iodine or of exposure to a goitrogen

TABLE I—SUMMARY OF 12 CASES OF NON-ENDEMIC GOITROUS CRETINISM

Case no	Sex	Age (yr)	Height (cm)	Bone age (yr)	Cholesterol (mg per 100 ml)	Electrocardiogram	State of thyroid	Teleradiograph of heart	Previous thyroid treatment	
1	M	$15\,^{7}/_{12}$	136 (*151 2*)	7–8	200	Low voltage, flat P and T	Diffuse firm goitre	C R 52%	—	
2	F	$11\,^{7}/_{12}$	108 (*141 6*)	4–5	321	Low voltage, flat P and T	Firm nodular goitre	C R. 61%	—	
3	M	$10\,^{1}/_{12}$	112 (*132*)	4–5	223	Low voltage flat P and T	Diffuse firm goitre	C R 65%	—	
4	F	$8\,^{3}/_{12}$	100 (*123 7*)	3–4	318	Low voltage, inverted T_1 and T_2	Diffuse goitre	C R 65%	—	
5	F	$7\,^{7}/_{12}$	93 (*119 9*)	2–3	184	Low voltage inverted T_3	Diffuse firm goitre	C R 60%	—	
6	F	20	149 8	16–17	400	Low voltage	Diffuse firm goitre	No enlargement	—	
7	M	16	123 (*157 8*)	13	500	Low voltage	Diffuse firm goitre	No enlargement	—	
8	M	$4\,^{8}/_{12}$	68 (*99*)	Under 1	150	Low voltage, flat P and T	Slightly enlarged	No enlargement	—	
9	M	$2\,^{9}/_{12}$	82 5 (*87 5*)	1	260	Low voltage inverted T_2	Slightly enlarged	No enlargement	—	
10	F	4	87 (*96 7*)	Under 1	236	Low voltage flat P and T	Slightly enlarged	C R 57%	—	
11	F	$6\,^{1}/_{2}$	98 (*112*)	3	139	—	Diffuse firm goitre	No enlargement	Yes $^{6}/_{12}$	Stopped $^{2}/_{12}$ before I^{131} studies
12	F	$3\,^{1}/_{2}$	88 (*93*)	3	122	—	Diffuse firm goitre	No enlargement	Yes $^{8}/_{12}$	

Notes —Cases 1 2 3 and 4 are siblings Case 5 is a cousin of 1–4 6 and 7 Cases 6 and 7 are siblings and cousins of 1–5 Cases 11 and 12 are half-sisters (same mother) Previous to thyroid treatment cases 11 and 12 showed much delayed ossification and hypercholesterolæmia (Dundee Royal Infirmary)

Height —Italic figures in parentheses are the average normal heights for children of the respective ages (taken from Holt s *Diseases of Infancy and Childhood*, 1911)

Teleradiograph of heart —C R =Cardiothoracic ratio

St. Thomas's Hospital Medical School

The 1953 edition of the list of old students can now be obtained from the medical school beadle (price 5*s.* 3*d.*, including postage).

Symposium on Stammering

A symposium on the speech re-education of the stammerer is to be held at Goldsmiths' College, New Cross, London, S.E.14, on Thursday, June 11, at 6.45 P.M., when students from the college's classes in speech correction will discuss the problems of the stammerer.

Allergy to Penicillin

Because she is allergic to penicillin, a midwife at Scunthorpe has had to leave her employment. Alderman George Canty, chairman of the health committee, reported to Lindsey County Council that the nurse had tried wearing rubber gloves and other remedies, but none was of any help. Asked if there was no possibility of her finding work in another field of nursing, Alderman Canty replied that penicillin was so widely used that she would find it difficult to avoid coming into contact with it.

Conference of Prison Medical Officers

This annual conference was held at the Home Office on May 22, with Dr. H. K. Snell, director of medical services, Prison Commission, in the chair. Dr. N. J. deV. Mather, consultant psychiatrist at Crumpsall Hospital, Manchester, read a paper on Schizophrenia in Relation to Criminal Behaviour; and Dr. W. J. Gray, medical officer to H.M. Prison, Maidstone. and Dr. D. A. Ogden, medical officer to H.M. Borstal Institution, Portland, opened a discussion on the Management of the Homosexual in Prisons and Borstal Institutions.

Society of Apothecaries of London

Welcoming the Lord Mayor and Sheriffs at a livery dinner held at Apothecaries' Hall on May 19, Sir Wilson Jameson, the master, described the society as the best cross-section of the medical profession. Having separated from the Grocers' Company in 1617, it now had one of the largest liveries; and all had joined it "for no other reason than that we love the old institutions of this country." In his response the Lord Mayor (Sir Rupert De la Bère, M.P.) spoke of the value of tradition, and of the spirit of fellowship and friendliness evident in the society. Of the future of this country he said that "the rest of the world will believe in us as long as we believe in ourselves." Dr. H. Seaward Morley, the senior warden, proposed The Guests, coupled with the name of Mr. Justice Danckwerts—which name, he said, was greatly honoured in the households of general practitioners. In such homes it was already attached to a number of objects, and it might well be further commemorated by the profession keeping St. Danckwerts' Day, perhaps on Jan. 1 or April 1. Mr. Justice Danckwerts, in reply, regretted the inhibitions of his judicial office: he might not comment on his own judgment; he might not indulge in politics; he could offer no views on corporal punishment; and he must not even talk about that sacred cow, the National Health Service. So he contented himself with comparing the times of our fathers with the present day, when, in Medicine as in Law, manners have become milder, and people less eccentric. Finally, Sir Wilson Jameson, in proposing the Master's Toast, reviewed the society's affairs: he mentioned the retirement of Mr. Dearman (bedel since 1946) after 52 years' service; the course of lectures held last November, which would be followed by another next November; the religious service to be held on Sunday, Oct. 25; the ladies' dinner on June 16; and the soirée on July 21, when Sir William Gilliatt would be made a master of midwifery and Sir Charles Harington, F.R.S. would receive the society's gold medal in therapeutics for his work on the synthesis of thyroxine. The society had been very happy in the past few months to give accommodation to the new College of General Practitioners. During the year large sums had been spent in maintenance but it was a duty and privilege to maintain a building which had stood some 300 years and had withstood two world wars. The present was a season of rejoicing; and despite all the stress and trouble afflicting the world we could catch glimpses of a more hopeful future—of which it was just possible that this year would see the beginning. He proposed, in the traditional words, The Worshipful Society of Apothecaries of London, may it flourish root and branch—bringing help to all—till time ceases.

International Congress of Rheumatic Diseases

This congress will be held in Geneva from Aug. 24 to 28, under the auspices of the La Ligue Internationale contre le Rhumatisme. Further particulars may be had from Prof. K.-M. Walthard, Institut de Physiatrie, Hôpital Cantonal, Geneva, Switzerland.

Diary of the Week

MAY 31 TO JUNE 6

Wednesday, 3rd

Postgraduate Medical School of London, Ducane Road, W.12
2 P.M. Dr. J. C. Broom: Leptospirosis.

Royal Society of Medicine, 1, Wimpole Street, W.1
5 P.M. *Section of History of Medicine.* Dr. J. Zelmanowits: Historical Note on the Simple Dementing Form of Schizophrenia. Dr. Henry J. John (Ohio): Jan Evangelista Purkinje, Czech Scientist and Patriot (1787–1869).

Thursday, 4th

Postgraduate Medical School of London
4 P.M. Dr. B. Ackner: Depression. (First of three lectures.)

Royal Society of Medicine
5 P.M. *Section of Endocrinology.* Dr. Patricia Benedict (Boston): Idiopathic Hypercalciuria. Dr. Felipe A. de la Balze (Buenos Aires): Klinefelter's Syndrome.

London Jewish Hospital Medical Society
8.30 P.M. (11, Chandos Street, W.1.) Prof. David Slome: Experimental Surgery.

Honyman Gillespie Lecture
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Mr. G. A. Pollock: Cerebral Palsy.

University of St. Andrews
5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. A. D. Peacock, D.SC.: Animal Parthenogenesis.

Friday, 5th

University of London
5 P.M. (Westminster Medical School, 17, Horseferry Road, W.1.) *Dr. de la Balze: Morphology and Histochemistry of* Normal Adult Testes: Changes under Œstrogens Therapy.

Postgraduate Medical School of London
2 P.M. Mr. W. R. Merrington: *Carcinoma of Breast.*
4 P.M. Prof. Robert Kark (Illinois): Albumin Exchange *in Health and Cirrhosis.*

Institute of Dermatology, St. John's Hospital, W.C.2
5.30 P.M. Dr. G. B. Dowling: Tuberculosis of Skin.

Institute of Obstetrics and Gynæcology
3 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Mr. J. Wrigley: Problem of Dysmenorrhœa.

Saturday, 6th

Institute of Obstetrics and Gynæcology
10 A.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.) Mr. C. MacIntosh Marshall: Joseph Price oration.

Appointments

Falkman, S. C. J., L.R.C.P.E., D.P.H.: asst. county M.O. and M.O.H., Sedgley urban district and Tettenhall urban district.

Johnson, F. H. W., M.B. Lond.: appointed factory doctor, Bawtry, Yorkshire.

Kennedy, A. R., M.B., B.SC. Manc., D.P.H.: asst. county M.O. for Staffordshire and M.O.H., Seisdon rural district.

Laughlin, John, M.B. Camb.: appointed factory doctor, Three Bridges, Sussex.

Ritchie, Jean, B.A., B.M. Oxfd, D.M.R.T.: radiotherapist, Colonial Medical Service, Malaya.

Weir, I. B. L., M.B., B.SC. Glasg., D.P.H.: M.O.H., Dundee.

East Anglian Regional Hospital Board:

Bennett, L. B. G., M.B. Camb.: surgical registrar, Great Yarmouth and Gorleston Hospital.

Luck, L. C., L.R.C.P.E.: anæsthetic registrar, West Suffolk General Hospital.

Lumsden, J. D., M.D. Manc.: anæsthetic registrar, united Norwich hospitals.

Prouse, F. H., M.D.: orthopædic registrar, East Suffolk and Ipswich Hospital and Ipswich Borough General Hospital.

Births, Marriages, and Deaths

BIRTHS

Herst.—On May 8, at Guy's Hospital, to Pamela Herst, M.B. (née Green), wife of Edward R. Herst, M.B.—a son (Ian Malcolm).

TABLE II—UPTAKE OF THE RADIO IODINE BY THYROID GLAND

Case no	Percentage of dose in thyroid at hours after administrations									Potassium thiocyanate

12	36	51	56	62	74	70	31	—	—	—	—	—

METHODS

Carrier-free radioactive I^{131}, prepared by the Atomic Energy Research Establishment, Harwell, was administered in water as a drink to each patient 2 hours after food The dose was 30–200 µC

The amount, corrected for decay, of I^{131} which accumulated in the thyroid gland was estimated by a simple technique

A Geiger Müller counter (General Electric Co type ' G M 4 '), shielded laterally and distally with 2 cm of lead, and standard electronic counting equipment (power unit, amplification and quench unit, and scaler) were used The number of gamma rays emitted in 5 minutes by the dose in 10 ml of water in a universal container placed 30 cm from the counter was determined At various intervals after the dose was given the number of gamma rays emitted by the thyroid gland was counted (table II) The patient was placed with the upper margin of the sternum 30 cm distant from the lower and anterior surface of the counter shield, and the anterior surface of the neck was held vertically Additional lead shielding (0 5 cm) intervened between the patient's trunk and the counter

In cases 1–4 and 8 the effect of an oral dose (1 or 2 g) of potassium thiocyanate on the amount of radio-iodine in the thyroid gland was observed

The urine was collected in divided periods over 48 hours in 8 of the 12 cases (table III) The bladder was emptied at the end of each period except in cases 8 and 9, in which urine was collected continuously through a Paul's tube fixed to the penis Samples of urine were counted in the beta liquid counter designed by Veall (1948) The amount of radioactive iodine excreted in each period was expressed as a percentage of the dose administered, a dilution of the stock radio iodine solution used being kept for estimation of the dose

Samples of blood were taken off into oxalated bottles at 24 hours in 4 cases and at 48 hours in 9 cases The plasma was separated by centrifuging, and the total radioactivity present in 5 ml samples made up to the counter volume (10 ml) was determined in the beta liquid counter and the result expressed as the percentage of dose administered per litre of plasma (table IV) The radioactivity of the protein-bound iodine of the plasma was determined by precipitation by trichloracetic acid (Sheline and Clark 1950, Goodwin et al 1951) 5 ml samples of plasma were used, and the proteins were precipitated by 10% trichloracetic acid, the precipitate was washed twice with 2% trichloracetic acid, redissolved in 2N NaOH and the volume made up to the counter volume Counts for at least 10 minutes were made on the total plasma-iodine samples, and 20 minutes on the protein-bound iodine samples

TABLE III—URINARY EXCRETION OF RADIOACTIVE IODINE

Case no	Percentage of radioactive iodine excreted in various periods (hr)						
	0–6	6–12	12–18	18–24	0–24	6–24	24–48
1	9 3%	—	—	—	59 6%	50 3%	27 0%

10	20 4%	11 8%	9 0%	6 8%	48 0%	27 6%	4 0%
11	—	—	—	—	—	—	—
12	—	—	—	—	—	—	—

3 ml samples of plasma from cases 11 and 12, who received 125 µC of I^{131}, were examined for butanol extractable iodine by a modification of the method of Taurog and Chaikoff (1948) The iodine was extracted by three washings of n butyl alcohol, the extract was treated twice with a solution of 5% Na_2CO_3 in 4N NaOH, and the mixture was allowed to separate The alcohol layer was separated and concentrated by heat to counter volume Counts were made for 20 minutes on the fraction of plasma extractable by butyl alcohol but not re extractable by treatment with the solution of 5% Na_2CO_3 in 4N NaOH

Samples of plasma from cases 5, 6, and 7, who received 200 µC of I^{131} were submitted to Dr J Gross and Mrs R Pitt-Rivers at the National Institute for Medical Research, Mill Hill, London, for analysis by chromatography of the radioactivity in a butanol extract of the plasma (Gross and Pitt-Rivers 1952)

TABLE IV—PERCENTAGE OF I^{131} PRESENT AS TOTAL PLASMA IODINE (T P I), PROTEIN-BOUND IODINE (P B I), AND BUTYL ALCOHOL EXTRACTABLE IODINE (B E I)

(Results expressed as per cent of dose per litre of plasma)

11	—	—	—	1 35	0 49	36%	0 36%
12	—	—	—	1 32	0 40	30%	0 25%

RESULTS

The uptake by the thyroid gland, the excretion by the kidney, and the amount in the plasma of radioactive iodine are shown in tables II, III, and IV respectively It will be seen not only that the thyroid glands of these patients accumulated radio-iodine from the blood stream, but also that most of them did so with abnormal rapidity and in excessive amounts The glands did not retain the radio-iodine but released it into the circulation, some of it in a chemical form which could be precipitated by trichloracetic acid and extracted by butyl alcohol

Dr Gross and Mrs Pitt Rivers reported that radioactivity was present in butyl alcohol extracts of plasma samples withdrawn from cases 6 and 7 at 24 and 48 hours, but the amount was insufficient to give an autoradiograph allowing identification of its origin Radioactivity was present in the butyl-alcohol extract from case 5 which was examined on a kieselguhr column The radioactivity was not elutable with 20% chloroform in butyl alcohol equilibrated with 0 05% NaOH but was removed from the column with water Its chemical identity remained unknown It was neither thyroxine nor triiodothyronine

DISCUSSION

Thyroid Uptake

In general the uptake of iodine by the thyroid gland suggests hyperthyroidism Direct comparison with the pe, should be warned to take carbohydrate in adequate mounts and not to miss a meal or a mid-morning or id-afternoon snack when on the road. He was more ubious about the suitability of a diabetic for driving a ublic vehicle or for piloting an aeroplane. He strongly issented from the view of another speaker that a lawyer as entitled to pick holes in the police surgeon's evidence, o get his client off.

Dr. G. M. KERR said that attention should be paid to oss of judgment and increased reaction-time, both of which preceded motor incoördination and might result n serious errors in driving.

Dr. LINDSEY BATTEN said that the legal casuistry nvolved in quibbles about the colour of the accused nan's eyes was calculated to keep any but the most tout-hearted doctor from venturing into court.

Dr. G. J. V. CROSBY said that it was often an invidious ask for a doctor to dissuade elderly private patients from continuing to drive. One of his patients who drove a high-powered car at a reckless speed was extremely annoyed at the advice that he should give up driving after he had had three blackouts in a year and had been found to have petit mal.

MANCHESTER MEDICAL SOCIETY

Pituitary Adenomata

AT a meeting of the section of medicine of the Manchester Medical Society, on Dec. 3, Sir GEOFFREY JEFFERSON, F.R.S., spoke on the Varying Behaviour of Pituitary Adenomata. He said that some pituitary adenomata behaved in a toxic fashion, while others were inert. The "toxic adenomata" produced gigantism, acromegaly, and basophilism—although he shared the general doubt about basophilism being primarily a pituitary disorder. The chromophobe adenomata produced varying degrees of hypopituitarism; some eventually caused a drift towards Simmonds's disease.

Sir Geoffrey based his remarks on 316 adenomata. He had operated on 250; 11 showed locally invasive properties. Sugar-tolerance curves had not shown any significant trends, though the toxic adenomata were more liable to give rise to glycosuria. Neither the metabolic-rate nor the eosinophil-count showed any uniform change. On the whole the urinary output of gonadotropins was more often reduced than that of the 17-ketosteroids. The dangers of operation were related more to hypothalamic disturbances than to acute stress syndromes. The enlarged sella turcica seen in radiographs gave an inadequate idea of the actual size of the adenomata, of which sizeable supra-sella extensions were extremely common—a fact easily demonstrated by pneumo-encephalography.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY

Outpatient Problems

AT a meeting of the Devon and Exeter Medico-Chirurgical Society on Dec. 18, Dr. W. A. LISTER spoke of common outpatient problems.

The first was that of the child who persistently coughed at night. This cough started about the age of 2, often after pertussis and pneumonia. The patient was intelligent, quick, alert, impatient, growing fast, and rather pale. Associated complaints were abdominal pains and persistent nasal catarrh. Inquiry revealed that the mother had taken the child to many doctors, hospitals, and clinics; but still the cough continued. In the causation these were the main factors: (1) an infective focus in the throat, nasopharynx, or sinuses; (2) a psychosomatic factor (the patient was often the only child of anxious parents); and (3) a dietetic factor, usually an intolerance of fat. If these patients are recognised as early asthmatics other things fell into place. Focal infection must be dealt with; this would improve but not cure the patient's condition. The psychological side should receive attention, perhaps at a child-guidance clinic. Dietetic measures consisted in reducing intake of fat and increasing intake of carbohydrate. Skin tests were disappointing; but common allergens, such as feathers, hair, and pollen, should be avoided as far as possible: the removal of the domestic cat sometimes produced striking improvement. The breathing exercises advocated by the Asthma Research Council were of great help.

Dr. Lister's second problem was that of the mild melancholic. Such patients often complained of vertical headache or pressure, or of boring pain in the temporal region. The condition was apt to follow the receipt of bad news and to occur in elderly men with an enlarged prostate. A carefully recorded history would often elicit evidence of previous attacks. Skin rashes, night waking in the small hours, and withdrawal of interest from customary occupations were characteristic. Organic disease must, of course, be carefully excluded before melancholia was diagnosed. Treatment consisted in attacking the night waking with phenobarbitone and countering the consequent morning hangover with 'Benzedrine.' (The depression was worse in the morning.) If these measures failed electroconvulsive therapy often succeeded.

Dr. Lister's third problem was that of back strain producing persistent and otherwise inexplicable pain. Such pain might be due to minor degrees of root irritation on the concave side of a scoliosis. Poker-back followed prolonged and unnecessary decubitus. Both types responded well to physiotherapy.

Dr. CHARLES WROTH deplored the lack of liaison by which the same patient might be repeatedly and unnecessarily examined radiographically in various clinics and hospitals, or even in the same hospital.

Reviews of Books

Heredity in Uterine Cancer

DOUGLAS P. MURPHY, M.D., F.A.C.S., assistant professor of obstetrics and gynæcology and research associate, Gynecean Hospital, Institute of Gynecologic Research, University of Pennsylvania. Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1952. Pp. 128. 16*s*.

Dr. Murphy is right in thinking it important to determine whether heredity plays a part in the ætiology of uterine cancer, not only from the point of view of the woman whose mother has died of the disease, and who is therefore apprehensive for herself, but also from the point of view of those who have to diagnose and treat it. This book describes a well-planned, controlled investigation into the cancer incidence of near female relatives (mothers, sisters, female first-cousins, and their mothers) of 201 women suffering from cancer of the uterus, no attempt being made to distinguish cancer of the cervix from that of the body. The author concludes "that there is evidence for a rôle of inheritance in uterine cancer"; but that the *quantitative effect is small* and has not been measured with high precision. He is also of the opinion that the factors which predispose to uterine cancer do not predispose in any significant degree to cancer in other sites, but that hereditary factors do play a part in the ætiology of cancer elsewhere in the body. No significant tendency to concentration in particular families could be detected. The study is similar in plan to that of Brobeck,[1] made in 1949, and in general the results are similar.

The data took nearly three years to collect and at least four years to analyse. Four field workers were employed, and 890 patients diagnosed as having cancer of the cervix were visited, in order to secure records of 201 cancer family groups. The control families, 215 in number, were obtained from a dental clinic (113), women's clubs (82), and volunteers (20) An investigation of this kind cannot be lightly undertaken—it takes time, costs money, and when completed leaves gaps which detract from the value of any conclusions which may be drawn However careful the planning of the inquiry—and this was done with the utmost care—uncertainties due to lack of verified information, death of the patients or their relatives inequalities of cancerous and control groups, and many other hazards are certain to creep in.

---

[1] Brobeck, O. Heredity in Cancer Uteri: A Genetical and Clinical Study of 200 Patients with Cancer of the Cervix Uteri and 90 Patients with Cancer of the Corpus Uteri. Aarhus, Denmark, 1949.

Even when such investigations point strongly to possible ætiological factors, the final proof must lie in biological experiment with material in which all or most of the factors can be controlled

The Principles and Methods of Physical Diagnosis

SIMON S LEOPOLD, M D, associate professor of clinical medicine, school of medicine and graduate school of medicine, University of Pennsylvania Philadelphia and London W B Saunders 1952 Pp 430 37*s* 6*d*

IN this book Dr Leopold has set out to describe the methods of physical examination with an account of how and why such methods achieve their purpose—in other words, to provide a physiological or pathological explanation of the mechanisms at work It is indeed a most laudable object and he has approached it with skill, producing a text full of clear and practical information supported by nearly 400 photographs, pictures, and diagrams It is a new and useful departure to include a chapter on the acoustic principles of the sounds from the thorax, written from the physicist's point of view, by a professor of electrical engineering This does not make very easy reading for the student, but will certainly, as the writer hopes, stimulate in him "a continual consciousness of the complexity of sounds in physicodiagnostic procedures" Not all the smaller books on physical diagnosis are such a direct guide to the first principles of clinical methods

The Infirmities of Genius

W R BETT, M R C S London Christopher Johnson 1952 Pp 192 18*s*

DOES genius depend upon some external stimulus, such as alcohol, illness, or drugs, or upon some abnormality of character, to produce its most brilliant results? The author discusses this question in a penetrating survey of the lives of fifteen famous literary figures, examining the work of each and relating it to his physical weakness or mental instability The essays are written with a nice choice of language, and have a charm and an interest that will delight the reader even though most of the subjects were hardly pleasant people

Carlyle's life was an endless conflict, unresolved and unresolvable Shelley was morbidly hypersensitive and drank large quantities of laudanum, his cruelty to his first wife drove her to suicide Swinburne was a drunkard who had epileptiform seizures, Poe fought the intolerable morbidity of his manic depressive state of mind by taking refuge in opium and alcohol, De Quincey, the self confessed opium eater, would consume an ounce of opium in a day Beaudelaire was a syphilitic with a taste for opium and hashish, he died paralysed and speechless The gentle, peaceful Charles Lamb in his youth had a mental breakdown that necessitated his temporary restraint, Balzac wrote his best works after he had developed symptoms of hypertension, Keats died riddled with tuberculosis Burns was a victim of rheumatic fever, Byron's life was blighted by a congenital club foot, Alexander Pope, a tiny hunchback, was a martyr to headaches and to asthma

But what glorious things they wrote! Unsuccessful authors may console themselves with the thought that the price they paid was high

Dictionnaire français-anglais anglais-français des termes médicaux et biologiques

PIERRE LÉPINE chef de service à l'Institut Pasteur London H K Lewis Paris, Éditions Médicales Flammarion 1952 Pp 830 63*s*

AT last we have a really good dictionary of medical and biological terms to facilitate communication between the French-speaking and the English-speaking worlds The French side of it is based on the 1949 edition of Garnier and Delamare, and the English on the 10th edition of *Dorland's American Pocket Medical Dictionary* and the 1945 edition of *Gould's Medical Dictionary* Consequently the spelling of English words is American, there is thus no item "œdema" (except under "edema") and these little catches have to be borne in mind Between the two alphabetical sections are useful lists of equivalent weights, measures, and temperatures The whole work has taken about five years to prepare and appears to have been very carefully done, but there are still a few errors and omissions

Lancisi's Aneurysms

Translated by WILMER CAVE WRIGHT, emeritus professor of Greek, Bryn Mawr College New York Macmillan 1952 Pp 362 $7 50

THE name of Giovanni Maria Lancisi, physician to three Popes and the greatest Italian clinician of the early 18th century, is remembered chiefly through his editing and publication, in 1714, of the remarkable anatomical plates of Eustachius which had been lost for 160 years His main work, however, was *De Aneurysmatibus*, posthumously published in 1728 and never previously translated in full into a modern language The translator has done her work well, giving the Latin text on the left-hand pages, opposite her very readable English translation She has also provided informative notes

Lancisi uses the term aneurysm to mean dilatation of the heart as well as dilatation of the arterial wall Some of his case notes and necropsy findings seem to relate to hypertensive heart failure He appreciates the relation of syphilis to aortic aneurysm and other forms of heart disease, and regards the prognosis as good "In order that I might extend immediate relief to the patient, I asked him whether he had ever been afflicted with the French disease, and when he replied that as a youth he had once been attacked by virulent gonorrhœa which ceased of itself, then I was inspired with the most confident hope that the sick man would soon convalesce from this terrible malady, that is, if he would for his part undergo the treatment with mercurials just as it has turned out so fortunately for me in other cases" He gives a clear description of right heart failure, the chronic bronchitis and asthmatic spasm impeding the flow of blood through the lungs

Lancisi was clearly a pioneer in the pathological study of heart-disease, and his book is a classic which will delight cardiologists

Any Questions ?

A Selection of Questions and Answers published in the BRITISH MEDICAL JOURNAL Second series London British Medical Association, Tavistock Square, W C 1 1952 Pp 195 7*s* 6*d*

THIS second series of answers to questions from doctors, like the first bears a superficial and disconcerting resemblance to those little volumes of likely questions and appropriate replies which the more anxious types among us used to con on the way to the examination rooms But a second glance removes this impression the questions are so much more perspicacious, searching, and practical than those set by examiners, and the replies come from informed and expert quarters A third thought which crosses the mind is that examiners might do worse than study this little book when deciding what to ask the student taking finals

---

Gas and Air Analgesia in Midwifery (2nd ed London *Staples Press* 1952 Pp 78 10*s* 6*d*)—Dr G H J Stown in the new edition of his little book, has despaired of describing every kind of anæsthetic machine now in use in this country though he has done his best to include pictures of most if not all of them By omitting the descriptions he has made room, without increasing the size of his little book, for a very short chapter on 'Trilene' (trichlorethylene), and a longer one on the care of the unconscious patient and the resuscitation of the newborn infant The cost of the book has doubled with the rising costs of publishing since 1946, but it is still within reach of modest purses It is designed to explain to midwives the principles underlying gas and oxygen analgesia, and to give them practical advice on its management, but it can also be read with profit by medical students results of other workers is difficult owing to considerable variations in the techniques used. By any standards, however, it is obvious that the thyroid glands of cases 1–4, 11, and 12, in which serial measurements were made, accumulated iodine more rapidly than normal, and that the greatest uptake was well above the normal range. The initial observations were incomplete in case 7 but suggested a similar trend. The uptake at 24 hours was abnormally high—i.e., above 55% (Werner et al. 1949, Goodwin et al. 1951) in only 2 of the 11 patients so studied (cases 3 and 8), but it is obvious that the peak uptake was often past by this time (cases 1, 4, 11, and 12). None of the patients showed an inability to take up iodine from the blood-stream into the thyroid gland. The administration of potassium thiocyanate, which leads to the discharge of any inorganic iodine present in the thyroid gland (Vanderlaan and Vanderlaan 1947), did not produce any detectable alteration in the radio-iodine content of the glands (cases 1–4 and 8). These results indicate that the thyroid glands could take up inorganic iodine from the blood and convert it into an organic form. They suggest also that the glands could release this organic iodine into the circulation.

Urinary Excretion

In contrast with the uptake of iodine by the thyroid gland, in no case did the amount of iodine excreted in the urine suggest hyperthyroidism. The amounts excreted in 24 hours were within the range reported in normal and hypothyroid people—i.e., 20–65% (Goodwin et al. 1951). Of the 8 patients so studied 6 excreted more than 25% of the ingested dose in 6–24 hours. Mason and Oliver (1949) consider that this result is characteristic of hypothyroidism. The large amount of iodine excreted in the urine in the period from 24 to 48 hours by at least 4, and probably 6, of these 8 patients also indicates hypothyroidism according to the findings of Arnott et al. (1949). So far as the present investigations are concerned, the amounts of iodine excreted in the urine are more consistent with the clinical state of the patient than are the amounts of iodine taken up by the thyroid gland. None the less, the intrinsic unreliability of urine collections and the particular difficulties met with in this type of patient detract from the value of studies of urinary excretion.

Plasma Radioactivity

The results of the plasma-radioactivity studies are unexpected in hypothyroidism. The total radioactivity present in the plasma at 48 hours exceeded 0·7% per litre in 8 of 9 patients. Goodwin et al. (1951) found that 0·7% per litre was the upper limit of normal. They found values in excess of 0·7% per litre in patients with thyrotoxicosis and toxic adenoma, in 1 patient with a cervical lipoma overlying the thyroid gland and a normal basal metabolic rate, and in 1 patient with Hashimoto's thyroiditis who had a basal metabolic rate of −20%. High values for total plasma activity at 24 hours were found in the 4 patients we examined. Williams et al. (1949) recorded similar results at 24 hours in both thyrotoxicosis and myxœdema.

Our results for protein-bound iodine obtained at 48 hours by precipitation by trichloracetic acid—0·1–0·5% per litre in 5 patients, and more than 0·5% per litre in 4 patients—are important. They should be compared with the figures found by Goodwin et al. (1951), in whose 2 cases of hypothyroidism protein-bound activity at 48 hours was negligible, and in only 2 of whose non-toxic subjects did it exceed 0·2% per litre. These workers consider that, if the amount of radio-iodine present in protein-bound form at 48 hours exceeds 0·5% of the dose per litre, the patient should be regarded as thyrotoxic, with the important reservation that abnormal results may be obtained in thyrotoxic patients who have been successfully treated and no longer show any clinical evidence of thyrotoxicosis. They report, but do not discuss, the result in the case of Hashimoto's thyroiditis, where the protein-bound activity at 48 hours was 2·3% per litre. Of the 4 patients in whom we estimated protein-bound activity at 24 hours the results were in the thyrotoxic range in 3 and in the normal range (Freedberg et al. 1949) in 1.

The value of the study of protein-bound iodine by a precipitation method as an index of thyroid function is based on the assumption that the protein-bound iodine so separated and estimated is essentially a measure of the thyroxine content of the plasma (Goodwin et al. 1951). Though the assumption is generally true it is not universally so (Blomfield et al. 1951). Our results in these cases of cretinism also discredit the general applicability of such an assumption.

The exact chemical composition of the compounds included with the protein-bound iodine fraction is unknown, but it appears that some diiodotyrosine may be precipitated with the proteins (Man et al. 1951). Rall (1950) has reported a case of myxœdema in which 27% of the plasma radioactivity at 48 hours was present as diiodotyrosine. The likelihood that diiodotyrosine is the basis of the radioactivity in the protein-bound iodine fraction in our cases has therefore to be carefully considered.

The results, in cases 11 and 12, of the butanol-extraction method, which is stated to remove any inorganic iodine and diiodotyrosine, but not thyroxine, from the butyl-alcohol extract (Taurog and Chaikoff 1948), are important. It is obvious that radioactivity persists in the butyl-alcohol extract, but the amount is less than that precipitated by trichloracetic acid. Clearly only a proportion of the radioactivity found by precipitation can be due to diiodotyrosine. The chemical basis of the remainder is unknown. On clinical grounds it is not thyroxine. The patients presented with the clinical picture of hypothyroidism and showed a striking response to dry thyroid given orally. There is therefore no evidence of tissue insensitivity to the thyroid hormone. The chromatographic studies of Dr. Gross and Mrs. Pitt-Rivers in case 5 support the opinion that the thyroid hormone, whether it be thyroxine or triiodothyronine, was not being released into the circulation. Though its chemical identity remains unknown, it is reasonable to assume that the radioactivity is present in a small organic molecule, probably in a protein molecule.

The plasma studies confirm the conclusions reached from the studies of thyroid uptake that the thyroid glands could take up inorganic iodine from the blood and convert it to an organic iodine compound. In addition they show that the glands could release iodine in an organic form into the circulation.

CONCLUSIONS

The thyroid uptake and plasma content of radioactive protein-bound iodine in our cases of non-endemic cretinism add to the anomalous results reported in other investigations of thyroid disorders by similar isotope techniques. They emphasise how important it is that no laboratory test should take precedence over clinical assessment of the patient. Most of the amounts of iodine taken up by the thyroid glands and some of the amounts of protein-bound iodine found in the plasma in our cases suggested hyperthyroidism and might readily, without reference to the clinical picture, have been interpreted as indicating thyrotoxicosis. The amounts of iodine excreted in the urine were most consistent with the clinical state. These results add weight to the advice offered by Goodwin et al. (1951) that, when radio-iodine is used, it is worth while to investigate every patient as fully as possible; but the conclusion of these workers that "the estimation of the protein-bound plasma activity 48 hours after a tracer

STEVENS-JOHNSON SYNDROME

REPORT OF A CASE

PETER W. GRANT
L.R.C.P.E.

DERMATOLOGICAL REGISTRAR, DERBYSHIRE ROYAL INFIRMARY, DERBY

FOLLOWING the original description of erythema multiforme exudativum by Hebra in 1866, Alibert and Bazin (1862) described lesions of the mouth, associated with general symptoms, and they distinguished a herpetic lesion of the iris. In 1922, Stevens and Johnson stated that the criteria for diagnosis were a generalised maculopapular eruption associated with ulceromembranous stomatitis, purulent conjunctivitis, and fever. In 1937 Klauder described a new symptom complex known in the French literature as ectodermosis erosiva pluriorificialis, and in 1938 Low and Davies reported a case "dermato-stomatitis" (Baader) complicating manic depressive insanity. In 1940 Behcet described a "triple symptom complex" consisting of aphthous ulcers in the mouth and on the genitalia and erosion of the cornea with iridocyclitis, associated with erythema nodosum. Lever (1944) described the development of cicatricial conjunctivitis and keratitis. Whatever the name used in these and other descriptions the conditions were very similar, varying only slightly from Hebra's original account. In fact certain authors (e.g., Billow and Lowen 1952, Thomas 1950) have suggested that the various synonyms should be dropped and Hebra's original title used. More recently upper respiratory and pulmonary complications (Finland et al. 1948) and severe anæmia (Alexander 1949) have been reported.

Anderson et al. (1949) tried to identify a virus by scarifying the eyes of rabbits with fluid from the vesicles. A conjunctivitis developed and cytoplasmic inclusion bodies were demonstrated, but this has not so far been confirmed by other workers. Finland et al. (1948) noticed lesions in the lungs resembling virus pneumonia in severe cases. Klauder (1937) pointed out similarities to foot-and-mouth disease but he was unable to identify the virus. Murray (1947) and Alexander (1949) isolated *Staphylococcus aureus* from the eyes, throat, and urethra, as was done in the case reported here. Certain authors have suggested allergy as a cause, but the evidence has not been convincing except perhaps in two instances. Thomas (1950) described a case which relapsed four times after a small dose of sulphonamide on each occasion, and Straus (1948) reproduced the syndrome by giving sulphonamides. On the other hand, Billow and Albin (1946) did not find any cases in a large number of people given sulphadiazine for a period of five weeks, but a fatality has been reported following the use of sulphadiazine (Nellen 1947).

The condition is commonest below the age of 30 but may occur at any age, and there is a preponderance of male patients (Ashby and Lazar 1951). The duration of the rash is usually about eighteen to twenty-one days (Nellen 1947). Recurrences and fatalities have been reported (Billow and Lowen 1952, Thomas 1950).

Treatment has in general been unsatisfactory and mainly symptomatic. In favourable cases the condition usually clears in three to four weeks. Claims have been made for sulphonamides and penicillin (Wright et al. 1947) but they have not proved of great value. Church (1950) and Lynas (1950) found that aureomycin produced dramatic improvement. A patient treated topically with cortisone did well (Fishman 1951), and adrenocorticotropic hormone (A.C.T.H.) has also been successful (Caldwell 1953).

CASE RECORD

A soldier, aged 20, reported to the skin department of a military hospital. He had been vaccinated for the first time ten days previously. The day before admission he had noticed a rash on his arms, legs, hands, feet, and body. He had felt unwell the previous night, and in the morning he felt shivery and his gums and tongue were painful. He had had no previous skin disease or serious illness. He had not been taking any drugs. His family history was negative.

He was a well built man who looked flushed and ill. The temperature was 100·8°F, pulse-rate 94, and respiration-rate 22. He had no generalised lymphadenopathy, but there were some palpable glands in the left axilla, presumably due to the vaccination. His tongue looked red and sore and was ulcerated in places. The gums were inflamed. The lips showed vesiculation and some crusting. The fauces were inflamed, with a few vesicles and small ulcers. He did not complain very much about his throat. The eyes, although he made no complaint about them, showed definite conjunctivitis with a slight purulent discharge and blepharitis. Over the insertion of the left deltoid there was a large crusted infected vaccination mark surrounded by a large area of erythema. Purulent material exuded from the edges of the crust.

The arms, forearms, palms, thighs, legs, and soles were covered with a diffuse erythematous eruption with numerous vesico papules. The lesions tended to coalesce at the wrists and there were many lesions scattered over the chest, abdomen, and back. Examination of other systems revealed no abnormality.

The day following admission he complained of irritation of the glans penis, frequency of micturition, and slight dysuria. He had a purulent balanitis and white urethral discharge.

Investigations.—Hb 94% (Sahli), red-cell count 5·2 million per c.mm., white-cell count 14,000 per c.mm. (polymorphs 82%), platelets 350,000 per c.mm. Clotting-time and bleeding-time normal. Blood-urea 24 mg. per 100 ml. Plasma-proteins normal. Blood culture negative. Erythrocyte-sedimentation rate 21 mm. in 1st hour (Westergren). W.R. negative. Swabs from throat, mouth, conjunctivæ, and vaccination grew *Staph. aureus*. Urethral smear showed gram-positive cocci, pus cells, and epithelial cells, and a culture grew *Staph. aureus*. The urine was cloudy with a heavy deposit in the first specimen in a two-glass test. It contained a few pus cells, and the deposit was urates. Fluid from one of the vesicles was sterile. Biopsy of a lesion showed changes consistent with a diagnosis of erythema multiforme. X-ray examination of the chest showed no evidence of disease.

Progress and Treatment.—Treatment was started with 'Sulphatriad,' 2 g. at once and 1 g. six-hourly. He had hydrogen peroxide mouth-washes, and a 1% aqueous solution of gentian violet was applied to the lips and gums; 10% 'Albucid' (sulphacetamide) drops to the eyes. The balanitis was treated with 1 in 4000 potassium permanganate. All these local applications were used frequently. Calamine cream was applied to the skin. He showed no response to the chemotherapy in forty-eight hours, so penicillin (200,000 units six-hourly) was given in addition. The pyrexia continued, ranging between 100° and 102°F, and he appeared to be becoming more toxic. He found difficulty in eating, but continued to take food and fluid by mouth. After a further three days, the mouth and eyes had improved slightly, and the balanitis was not so troublesome, though the urethral discharge remained the same. In spite of this improvement his general condition was unchanged. The skin lesions had in some areas begun to fade but fresh crops appeared, some of them hæmorrhagic. As his general condition was not responding, it was decided to stop the penicillin and sulphatriad, and to give a course of chloramphenicol. The dosage was 1 g. to start with and 500 mg. four-hourly, supplemented by vitamin B_1 (6 mg. four-hourly). This produced an almost dramatic response, and within thirty-six hours his temperature was normal and remained so. Within three days, the urethral discharge had cleared, the balanitis had almost gone, the mouth and eyes had much improved, and the skin lesions were drying up and flaking off, the palms and soles being last to clear. After five days the dose of chloramphenicol was reduced to 250 mg. eight-hourly, and stopped altogether after eight days when all signs had gone except for slight flaking of the skin on the palms and soles. Ten days later he was discharged from hospital, and when seen one month later he was well and had had no recurrence.

DISCUSSION

This case showed the commoner signs necessary for a diagnosis of Stevens-Johnson syndrome—i.e., a rash dose of radioactive iodine is essentially a measure of the amount of circulating thyroxine" must be accepted with even greater reserve than they suggest.

The results of our investigations confirm the American reports (Hamilton et al. 1943, Lerman et al. 1946, Stanbury and Hedge 1950, Stanbury 1951) that the thyroid glands of cretins with non-endemic goitre are hyperactive and accumulate radio-iodine administered orally more rapidly and to a greater degree than normal. In some of the American cases there was definite evidence that the thyroid glands could not convert inorganic iodine into an organic form (Stanbury and Hedge 1950, Stanbury 1951), and in others there was evidence that the thyroid glands could form thyroxine but could not release it into the circulation (Hamilton et al. 1943). Our patients clearly differ from those described by Stanbury and his colleague in that the glands converted the inorganic iodine into an organic form. We have not had the opportunity to examine any of the glands after removal by operation, because we have not found thyroidectomy to be necessary in any of our patients. We cannot therefore state dogmatically that our patients differ from those described by Hamilton and his associates, since we have no information about the chemical form in which the iodine is present in the glands. Probably our patients do differ. Our results suggest that our patients could release the radio-iodine in an organic form into the circulation.

Our investigations indicate that non-endemic goitrous cretinism may be caused by an inability of the thyroid gland to complete the synthesis of the thyroid hormone. The defect which we have discovered has apparently not been previously described. The nature and cause of the defect are obscure. It is probably intrinsic, and there is evidence that it may be familial.

SUMMARY

The results obtained with radioactive iodine (I^{131}) in 12 cases of non-endemic goitrous cretinism are recorded and discussed.

Most of the amounts of I^{131} taken up by the thyroid gland and some of the amounts of protein-bound iodine found in the plasma suggested hyperthyroidism, and might readily, without reference to the clinical picture, have been interpreted as indicating thyrotoxicosis, whereas the amounts of iodine excreted in the urine were most consistent with hypothyroidism.

The thyroid glands of the patients took up inorganic iodine from the blood-stream and incorporated it into an organic form. An organic iodine compound, not thyroxine, was released into the circulation. Its chemical nature is unknown, but it is present in that fraction of the plasma which is extractable by butyl alcohol but not re-extractable by treatment with the solution of 5% Na_2Co_3 in 4N NaOH.

It has been shown that non-endemic cretinism may occur in the presence of a thyroid gland which is able and eager to take up and convert inorganic iodine to an organic form, and it is postulated that in such cases there may be an intrinsic, probably familial, defect in the final synthesis of the thyroid hormone.

Thanks are due to Prof. J. L. Henderson for allowing us to study cases 11 and 12; Dr. J. Gross and Mrs. R. Pitt-Rivers for the chromatographic studies; the Board of Management, Glasgow Royal Infirmary, and the Rankin Fund, Glasgow University, for defraying the expenses of the radio-iodine studies; and the nurses of the two hospitals for their coöperation.

like erythema multiforme, stomatitis, conjunctivitis, and urethritis The interesting points are the preceding vaccination and the response to chloramphenicol

Common Lesions—Eye lesions are almost always present—usually a conjunctivitis with exudate and usually bilateral There may be œdema of the lids and blepharitis Cases of keratitis severe enough to cause blindness have been reported (Lever 1944), although with the use of chemotherapy this may be reduced (Goldfarb 1946) The lips are always involved and show erythema, swelling, fissuring, ulceration with hæmorrhage, and residual crusting Buccal lesions are almost always present, and may show a pseudomembrane or ulceration and vesiculation involving the tongue, palate, fauces, and pharynx Penile or vulvo-vaginal lesions with erythema, œdema, and vesiculation, with or without non-specific urethritis, are also common The rash is most often maculopapular, vesicobullous, or hæmorrhagic It is usually generalised in distribution but the scalp often escapes

Rarer Signs—Pneumonic lesions have been reported in the U S A by the Commission on Acute Respiratory Diseases (1946), Finland et al (1948), and Billow and Lowen (1952), and in this country by Church (1950) Sore throat, with or without dysphagia, and joint pains are occasional features, and erythema nodosum sometimes appears

Differential Diagnosis—The condition has to be distinguished from the other bullous and vesicular dermatoses and exanthemata These include the pemphigus group, dermatitis herpetiformis, the herpes group, bullous erythema multiforme, Kaposi's varicelliform eruption, vaccinia, varicella, and variola Drug eruptions should be considered, such as those due to arsenic, barbiturates, bromides, iodides, phenolphthalein, and quinine

I can find no report of the syndrome following vaccination, although a case of erythema multiforme complicating vaccination has been reported

The cause of this condition is still unidentified, and the treatment is mainly symptomatic, although chemotherapy will reduce secondary infection and probably prevent serious eye complications In the future cortisone and A C T H may provide the answer (Fishman 1951)

SUMMARY

A soldier, aged 20, fell ill with a case of Stevens-Johnson syndrome ten days after vaccination He was successfully treated with chloramphenicol

I am indebted to Dr P D C Kinmont for his helpful criticism

ROYAL SOCIETY OF MEDICINE

Fertilisers versus Organic Manures

THE section of comparative medicine met on May 20, with Prof C L OAKLEY, the president, in the chair

SIR WILLIAM OGG (Rothamsted Experimental Station, Harpenden) explained the history of fertiliser development While manure was used from ancient times, liming came very much later, and it was only after 1842, when John Bennett Lawes, the founder of Rothamsted, patented his water-soluble superphosphate fertiliser and showed it was better than the ground bones previously used, that research began into the best way to use different fertilisers for different crops on different soils This coincided with a time of great increase in population, and the urbanisation of Britain, which in turn meant that sewage from the towns went into the sea instead of restoring valuable chemical elements to the land Now the motor car had replaced the horse, and the quantity of animal feeding-stuffs imported annually had fallen to half the pre-1939 figure England and Wales now made about 35 million tons of farmyard manure a year, which represented about a third of all the nitrogen, a quarter of the phosphate, and half the potash actually added to the soil by farmers today Most of the recent increase in British food production was due to better fertiliser practice, and a survey had shown that many farmers still had a great deal to learn and could further increase their yields by using the correct fertiliser in the right time and place Before the war Holland used five times as much fertiliser annually as did Britain, and other European countries had similar figures

Proponents of "organic" farming differed in their degree of opposition to the use of chemical fertilisers some would permit basic slag (just as some teetotallers drink invalid port), but they all believed that manure had a vital principle lacking in all chemicals, and therefore that plants grown without it were inferior in nutritive quality and in resistance to disease The scientific evidence did not support this view Many plants could be grown in pure mineral solutions (hydroponics) even when special precautions were taken to eliminate soil bacteria on their roots Soil diseases were distributed quite differently from the areas of greatest use of fertilisers, and Rothamsted experiments had shown that nitrogenous fertilisers actually made wheat more resistant to some diseases Nor did fertiliser increase soil erosion The broad balk field at Harpenden had been heavily dressed with chemicals for the past 110 years, yet crops were still good, root and stubble organic matter was still available for ploughing in, and the soil microbe count was high (although in general very high counts did not necessarily mean better crops)

Fertilisers were essential for large crops because manure and compost could never supply much more than 10% of the need Town refuse and sewage sludge were inferior to good dung and too bulky to transport far To grow crops specially for composting was very uneconomic in land and labour This stated the British position, but it had to be remembered that soils in many parts of the world were naturally deficient in phosphorus, potash, or trace elements, and agriculture only became possible when these lacks had been made good with chemicals

Fertilisers were flexible in use, but required intelligent application, mistakes were possible Organic manures worked more slowly and sometimes gave the wrong balance of nutrients, but were nearly foolproof The two were not mutually exclusive but were complementary, and the best farming practice employed both

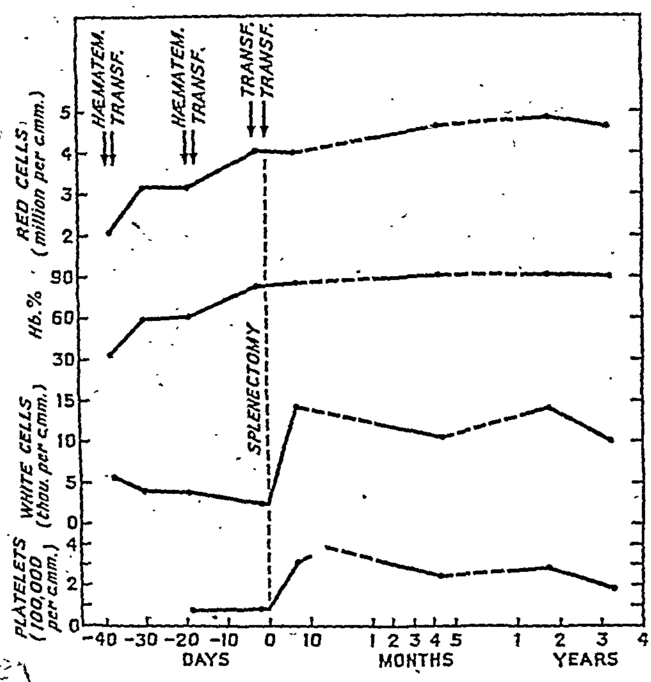

Fig. 2—Blood picture before and after splenectomy in portal hypertension with extrahepatic obstruction.

and of the bone-marrow in conditions associated with enlargement or increased activity of splenic tissue, such as may be observed in portal hypertension or in idiopathic thrombocytopenic purpura.

The term "hypersplenism" has been applied to the clinical picture in which it is believed that overactivity of the spleen results in reduction of one or more of the formed elements of the peripheral blood or delayed maturation of their precursor cells in the bone-marrow. This rôle of the spleen has been discussed by Limarzi and Schleicher (1940) Limarzi et al. (1943), Dameshek and Estren (1947), Robson (1949), and Schatken (1952). In certain cases it has been shown that splenectomy can bring about rapid and lasting improvement in the abnormal hæmatological picture.

The syndrome of portal hypertension is now well recognised. It is characterised by splenomegaly and peripheral blood changes, of which the commonest are granulopenia and thrombocytopenia; in most cases by evidence of hepatic cirrhosis; and by a tendency to recurrent bleeding into the gastro-intestinal tract. These hæmorrhages, which usually present as hæmatemeses sufficiently severe to threaten the life of the patient, occur from veins in the cardio-œsophageal area which have become dilated and congested in an attempt to provide alternative channels by which blood may return from the obstructed portal bed to the general circulation.

TABLE I—CLINICAL DETAILS OF CASES IN WHICH THE SPLENIC ARTERY WAS TIED

Case no.	Disease	Main symptom	Site of ligature	Clinical effect
1	Hepato-lienal fibrosis	Ascites and hæmatemesis	Main trunk near hilum	No effect on progress of disease
2	Hepato-lienal fibrosis	Hæmatemesis	Main trunk above pancreas	Bleeding recurred 12 mos. later, no change in spleen size
3	Extra-hepatic block	Hæmatemesis	Main trunk and left gastro-epiploic	No bleeding in 18 mos., no change in spleen size
4	Hepato-lienal fibrosis	Hæmatemesis	Main trunk and left gastro-epiploic	Bleeding recurred 2 yr. later, spleen showed central infarct
5	Cirrhosis	Ascites	Main trunk above pancreas	No effect on progress of disease or on spleen size. Hæmatemesis 18 mos. later

In portal hypertension the main objective of surgical treatment is to prevent the recurrence of serious hæmorrhage by reducing the portal venous blood-pressure or by diverting the portal blood from the dangerous cardio-œsophageal region. Such operations as splenectomy and ligation and division of the splenic arterial supply may lower the portal venous pressure by reducing the volume of arterial blood entering the portal bed. Other operations are designed to establish a large portal-systemic venous communication, such as is provided by anastomosis of the portal vein to the inferior vena cava, or of the splenic vein (after splenectomy) to the left renal vein; these, when successful, achieve the double purpose of lowering portal pressure and of diverting portal blood from the site of the varices. Excision of the varix-bearing area in the lowest 6–8 cm. of the œsophagus and the adjoining fundus and lesser curvature of the stomach is another procedure designed to remove the source of the hæmorrhages, probably without significant reduction of the portal pressure. Splenectomy is done at the same time if the spleen has not already been removed.

A second aim of surgical treatment is to improve the blood picture where there is persistent and severe reduction in the number of circulating leucocytes and platelets.

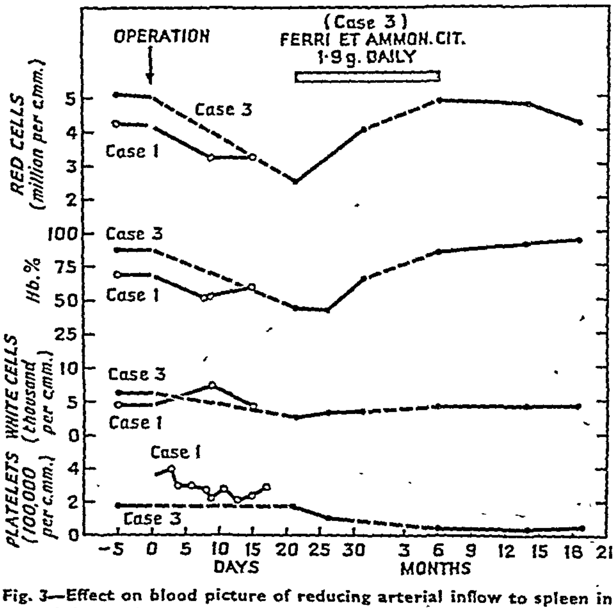

Fig. 3—Effect on blood picture of reducing arterial inflow to spleen in case 1 (hepatolienal fibrosis) and case 3 (extrahepatic obstruction).

HÆMATOLOGICAL CHANGES

It is with certain hæmatological problems of the portal hypertension syndrome that this paper is concerned. 12 cases of portal hypertension are reported in which the surgical treatment did not involve splenectomy: in 7 of these cases the aim of operation was to relieve the portal hypertension by anastomosing the portal vein to the inferior vena cava; and in 5 to reduce the splenic blood-flow by ligation of the splenic artery. In these 12 cases the changes in the peripheral blood picture after operation are compared with those observed after operation in 46 cases of portal hypertension in which splenectomy was done either as the only procedure or as a preliminary to spleno-renal anastomosis.

Mr G C **Ainsworth** PH D (University College of the South-West, Exeter), discussed factors in plant health and growth All agriculture was artificial since it forced plants to grow in pure culture instead of in the associations of mixed species characteristic of different soils and climates in Nature While some plants grew very well in inorganic water culture, others needed symbiotic bacteria or moulds for full growth Lucerne seed had to be inoculated naturally or artificially with root-nodule-forming bacteria In afforestation the newly planted young trees usually carried enough of the necessary symbiotic fungus or mycorrhiza on their roots, but sometimes it was necessary to add cultures to the soil Some cultivated plants grew well independently of the microflora of the soil, while others relied on it In the same way no simple generalisation was possible on the beneficial or adverse effects of fertilisers Adding potash to the soil decreased the rate of attack of the fungus causing chocolate spot in broad beans On the other hand green manure, such as grass cuttings, decreased the incidence of fungal potato scab by encouraging the growth of saprophytic fungi which competed with the pathogens and perhaps eliminated them by antibiotic action Plants could absorb antibiotics from the soil, and lettuce, for instance, had thus been made more resistant to grey mould

Dr D. P **Cuthbertson** (Rowett Research Institute, Aberdeen) said that adding excess of potash to the soil lowered the magnesium content of crops and animals feeding thereon were more subject to tetany But in general fertilisers made very little difference to crop quality They might affect the ratios in which certain proteins were made in the plant but they did not change the fundamental amino acid composition of the proteins Cows and other ruminants in any case gained a part of their dietary protein from the synthetic activity of microbes in their forestomachs The vitamin-C content of plants depended mainly on their genetic inheritance and varied to only a trivial extent with climate, soil or fertiliser McCarrison's claim, prior to 1924, that B vitamins were richer in wheat and millet manured with cow dung had not been substantiated by later, statistically sounder, experiments As for human health—a term very difficult to clarify and define—infant mortality was lowest and the expectation of life greatest in countries which used the most synthetic fertilisers, though of course there were many reasons for this hygienic triumph

Sir **James Scott Watson** (National Agricultural Advisory Service, London) pointed out that farming was lore as well as science British agriculture a century ago was world-famous for its success It was the result of about 8000 years of experience and tradition, and the yield of wheat averaged 11 cwt per acre In 1952 the average was 20 cwt, and this increase was due to science Traditional lore often worked well on its native heath but was disastrous when exported unless science was available too The loss of 50 million acres of good U S farming land through soil erosion was the result of attempting to follow Western European farming practice in the totally different climate of America The physical structure of soil determined its water-holding power, its ease of drainage, and the degree of diffusion of oxygen and carbon dioxide to and from plant roots Soil erosion—the washing away of a powdery topsoil by a deluge of rain—could be mitigated by proper land use and engineering by terracing and contour ploughing, sometimes by growing a cover crop at some season merely to break the impact of heavy raindrops or by agreeing that forest was the only practicable cultivation in a particular area Another approach was to study the binding agents in soil which led to a satisfactory crumb structure Decaying organic matter was important here, but unfortunately it was an unstable system Humus formation varied with bacterial activity, which depended on the nitrogen content of the organic matter Straw was low in this and slow to decay, vetch and clover high in it and fast to decay Good results in practice came from ploughing in certain grass/clover mixtures Plastics had been developed to fix the unstable soil at its best crumb structure, but they were too expensive for farm use Much older was the custom of mixing clay with sandy soils, or marling (adding clay and limestone), or mixing in subsoil by deep ploughing Present-day emphasis was on soil physics rather than soil biology The microflora seemed on the whole to look after itself, and as Sir William Ogg had pointed out it was weathering and not bacterial action that liberated most mineral nutrients for plant use

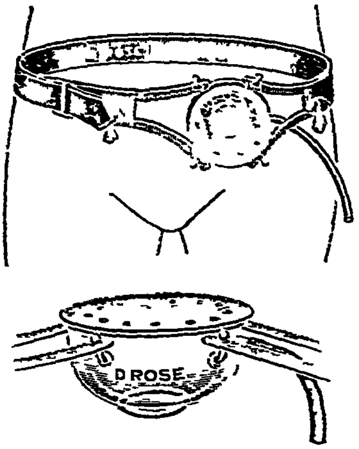
In the discussion the supporters of organic manures presented their views, but most speakers seemed to agree that the scientific evidence was against an extreme stand It seemed in any case to be quite inapplicable to countries such as Australia, where mineral deficiencies in the soil were of prime importance

New Inventions

SUCTION APPARATUS FOR ABDOMINAL FISTULÆ

The apparatus illustrated was originally devised for dealing with a small-bowel fistula opening on the abdominal wall Small-bowel contents rapidly excoriate the skin, and continuous suction applied through a tube placed in the fistula may delay closure

The hole in the base of the cup is centred over the fistula, its special rim ensures watertight closure, and tulle gras can be used to protect the skin within the bottom of the cup The contents are continuously withdrawn through the side-tube by connecting it to an electric sucker The lid is perforated so that no negative pressure is built up



Small-bowel, pancreatic, and biliary fistulæ have all been treated with this simple apparatus It reduces wastage of dressings, and both patient and nurses welcome its use The patient feels dry and comfortable and can sleep undisturbed by frequent dressings

I am indebted to Mr Donald Rose of 36, George Street, Portman Square, London, W 1, for making this apparatus for me

" . The prime motive in the creation of a Teaching University at the beginning of the century was to bring examination and thereby instruction into line with research But that meant something more than an opportunity to see that the graduate was informed of the latest discoveries It meant the opportunity to practise at all levels the art of enquiry Our offence is the offence of which academic societies have all too often been guilty, the ancient error of those whose chief distinction it was 'to know and enforce all of the right answers rather than to know or to ask any of the right questions' "—Prof. H. **Hale Bellot**, the vice chancellor, *University of London Gazette*, April, 1953, p 72

Effects of Splenectomy

The effect of splenectomy in such cases is illustrated in figs. 1 and 2 :

In a case of hepatolienal fibrosis with an enlarged spleen the preoperative blood picture showed the characteristic anæmia, granulopenia, and thrombocytopenia (fig. 1). Two months before operation hæmatemesis further lowered the hæmoglobin level, which rose rapidly after transfusion and iron by mouth. Immediately after splenectomy the polymorph and platelet counts increased, the white-cell count reaching a peak on or about the fourth postoperative day, and the platelets on the fourteenth day. Thereafter, over a period of months, the numbers of both the leucocytes and platelets decreased, though in neither case to as few as they had been before operation. The red-cell count and hæmoglobin value gradually increased over a long period.

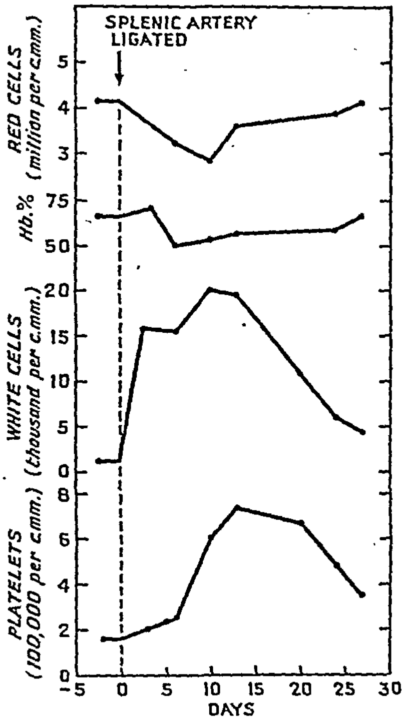

Fig. 4—Blood picture before and after operation in case 4 (hepatolienal fibrosis) in which ligation and division of the splenic and gastro-epiploic arteries caused a massive splenic infarct.

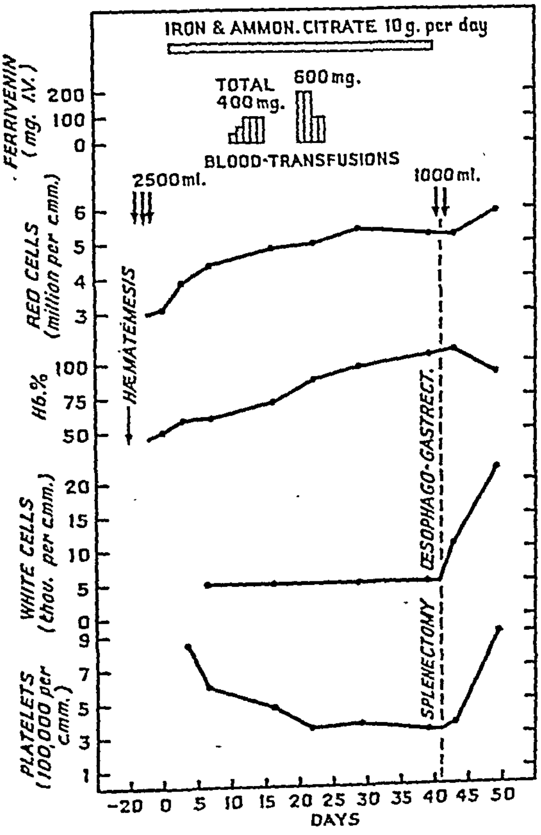

Fig. 5—Blood picture in case 4 twenty-six months after fig. 4, showing response to iron and to splenectomy.

When the splenomegaly and portal hypertension have been associated with extrahepatic portal obstruction, the peripheral blood presents a similar picture and reacts in a similar manner after splenectomy (fig. 2).

Effects of Ligation of Splenic Artery

Where splenectomy is not considered desirable, because of the poor general condition of the patient or the discovery at operation of extensive perisplenic adhesions, ligation of the splenic artery has been advocated as a less formidable operation (Blain 1918). The clinical details of 5 patients in whom such ligation was done are summarised in table I. Three different operations were used : in 2 cases ligation and division of the splenic artery on the upper border of the pancreas ; in 1 case ligation near the hilum of the spleen ; and in 2 cases ligation and division of the splenic and gastro-epiploic arteries. A record of 2 of the patients (case 3 with an extrahepatic block and case 1 with hepatolienal fibrosis), upon whom repeated blood-counts were done after operation, is shown in fig. 3. In both cases there was a postoperative decrease in erythrocytes and hæmoglobin, but in neither was there an increase in leucocytes or in platelets such as occurs after splenectomy. Cases 2 and 5, in which blood-counts were done less frequently, also showed no significant hæmatological changes after operation. In case 3 the continued presence of an enlarged spleen did not prevent a satisfactory response of the anæmia to iron by mouth.

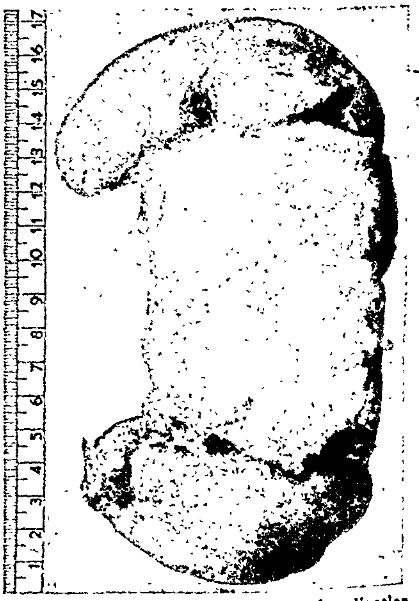

Fig. 6—Spleen removed 28 months after ligation and division of splenic and gastro-epiploic arteries, showing massive central infarct. (Scale in centimetres.)

In only 1 of the abovementioned 5 cases (case 4, with hepatolienal fibrosis) did a noticeable improvement in the peripheral blood picture follow splenic arterial ligation (fig. 4). There was an immediate increase of white-cell and platelet counts to large numbers, but after four weeks they had decreased to figures only slightly greater than those before operation. Two years later hæmatemesis recurred. There was an immediate posthæmorrhagic thrombocytosis, and the anæmia responded quickly and satisfactorily to iron therapy (oral and parenteral) (fig. 5). Splenectomy combined with limited œsophagogastrectomy was followed by typical postsplenectomy changes in the peripheral blood which were similar to those twenty-eight months previously after splenic arterial ligature. The appearance of the spleen removed at operation (fig. 6) provides a clue to the initial response ; there was a large central infarct with, above and below it, segments of living spleen which showed the classical histological changes of hepatolienal fibrosis described by McMichael (1934). Arterial ligations probably seldom produce actual infarction of the spleen or even any material reduction in the volume like erythema multiforme, stomatitis, conjunctivitis, and urethritis The interesting points are the preceding vaccination and the response to chloramphenicol

Common Lesions—Eye lesions are almost always present—usually a conjunctivitis with exudate and usually bilateral There may be œdema of the lids and blepharitis Cases of keratitis severe enough to cause blindness have been reported (Lever 1944), although with the use of chemotherapy this may be reduced (Goldfarb 1946) The lips are always involved and show erythema, swelling, fissuring, ulceration with hæmorrhage, and residual crusting Buccal lesions are almost always present, and may show a pseudomembrane or ulceration and vesiculation involving the tongue, palate, fauces, and pharynx Penile or vulvo-vaginal lesions with erythema, œdema, and vesiculation, with or without non-specific urethritis, are also common The rash is most often maculopapular, vesicobullous, or hæmorrhagic It is usually generalised in distribution but the scalp often escapes

Rarer Signs—Pneumonic lesions have been reported in the U S A by the Commission on Acute Respiratory Diseases (1946), Finland et al (1948), and Billow and Lowen (1952), and in this country by Church (1950) Sore throat, with or without dysphagia, and joint pains are occasional features, and erythema nodosum sometimes appears

Differential Diagnosis—The condition has to be distinguished from the other bullous and vesicular dermatoses and exanthemata These include the pemphigus group, dermatitis herpetiformis, the herpes group, bullous erythema multiforme, Kaposi's varicelliform eruption, vaccinia, varicella, and variola Drug eruptions should be considered, such as those due to arsenic, barbiturates, bromides, iodides, phenolphthalein, and quinine

I can find no report of the syndrome following vaccination, although a case of erythema multiforme complicating vaccination has been reported

The cause of this condition is still unidentified, and the treatment is mainly symptomatic, although chemotherapy will reduce secondary infection and probably prevent serious eye complications In the future cortisone and A C T H may provide the answer (Fishman 1951)

SUMMARY

A soldier, aged 20, fell ill with a case of Stevens-Johnson syndrome ten days after vaccination He was successfully treated with chloramphenicol

I am indebted to Dr P D C Kinmont for his helpful criticism.

* After adequate iron therapy.

of functioning splenic tissue. Histological examination of the spleen was possible in 3 patients on whom splenectomy was done subsequently. Only in the case already described did infarction occur. The changes observed in the other spleens and in the viable portions of the infarcted spleen were those usually found in portal hypertension. In none of the 5 patients did the spleen decrease in size after ligation of the splenic artery.

Effects of Portacaval Anastomosis

Portacaval anastomosis was done in 7 patients with portal hypertension; their hæmatological records are shown in table II. In 3 cases the spleen was considerably smaller after operation, and in every case there was direct or circumstantial evidence that the anastomosis remained patent. No significant change in the peripheral blood picture, other than that which might be expected from the relief of hæmorrhage and the administration of iron, accompanied these changes in the spleen and portal circulation. In case 8, where the patient presented the typical picture of hepatolienal fibrosis, transfusions effected an improvement in the red-cell count but portacaval anastomosis did not affect the leucopenia and thrombocytopenia (fig. 7). A month later splenectomy was followed by the characteristic and predictable changes in the peripheral blood. Histological examination of the spleen showed that the venous congestion had been completely relieved but that there was an intense cellular hyperplasia of the pulp.

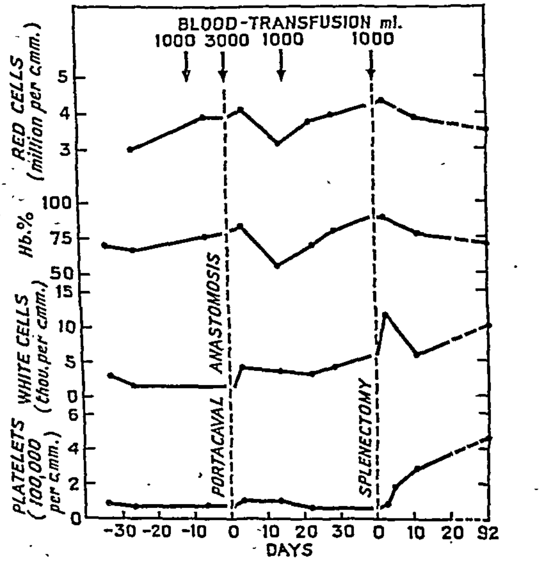

Fig. 7—Effect on blood picture of portacaval anastomosis and splenectomy in case 8 (hepatolienal fibrosis).

CONCLUSIONS

Observations in 46 cases of portal hypertension treated either by splenectomy alone or by splenectomy and splenorenal anastomosis indicate that the persistent leucopenia and thrombocytopenia found in this syndrome are rapidly relieved by splenectomy. These findings suggest a relationship between the levels of the leucocytes and platelets in the peripheral blood and enlargement or functional overactivity of the spleen, and is in accordance with the hæmatological concept of "hypersplenism."

After portacaval anastomosis the spleen became smaller in 3 cases from relief of venous congestion, but the pulp hyperplasia persisted, and in no case was the blood picture improved.

The effects of ligation of the splenic arterial supply by various operations were observed in 5 cases. The spleen did not decrease in size after any of these operations. Histological examination of the spleens of 3 patients in whom the splenic artery had been ligated and divided fifteen, eighteen, and twenty-eight months previously, showed either the typical changes of portal hypertension or complete localised infarction. The generalised atrophy of splenic tissue described by other workers (Watson 1935, Blain and Blain 1950) has not been observed. After splenic arterial ligation no improvement was noted in the blood picture except in 1 case in which there was extensive infarction of the spleen.

Neither relief of portal venous congestion by a portal-systemic venous anastomosis nor reduction in the blood-supply to the spleen by arterial ligation improves the leucopenia or thrombocytopenia characteristic of portal hypertension. In contrast the changes can be regularly relieved by splenectomy. Hence it may be inferred that the reduction in the leucocytes and platelets is directly related to some influence derived from the cellular components of the enlarged spleen.

In no case was there any evidence that any of the operations benefited the red-cell and hæmoglobin levels other than by control and prevention of œsophageal bleeding.

The observations recorded here were made on patients in the Royal Infirmary of Edinburgh and in the Presbyterian Hospital, New York, where one of us (A. I. S. M.) worked with Dr. Arthur H. Blakemore as a Rockefeller Foundation travelling fellow. Most of the hæmatological investigations were made by Miss Sheila T. Lindsay, B.SC.

NUFFIELD RESEARCH ASSISTANT TO THE OBSTETRIC UNIT, UNIVERSITY COLLEGE HOSPITAL, LONDON

The advantages to the obstetrician of a continuous recorder or indicator of the rate and regularity of the fœtal heart are so evident that attempts have been made to make a satisfactory clinical instrument ever since the electrocardiograph was designed by Einthoven in 1903. Early workers were disappointed with their results, although they tried œsophageal, vaginal, and rectal electrodes and turned their attention to recordings of the equine fœtus and chick embryos in the shell. The advent of the valve amplifier gave a new impetus to the subject, and some recordings were obtained as early as 1923 from the human abdominal surface.

The whole subject is most thoroughly reviewed by Bell (1938) who himself built an equipment in 1938. His conclusions were as follows:

> "One $^1/_3$ of 32 cases showed positive results, but the other $^2/_3$ did not show any wave which could definitely be recognised as fœtal. It is suggested that the failure to secure positive results in all cases is due partly to differences in the electrical properties of the abdominal wall and partly to the electrical disturbances produced by the abdominal muscles."

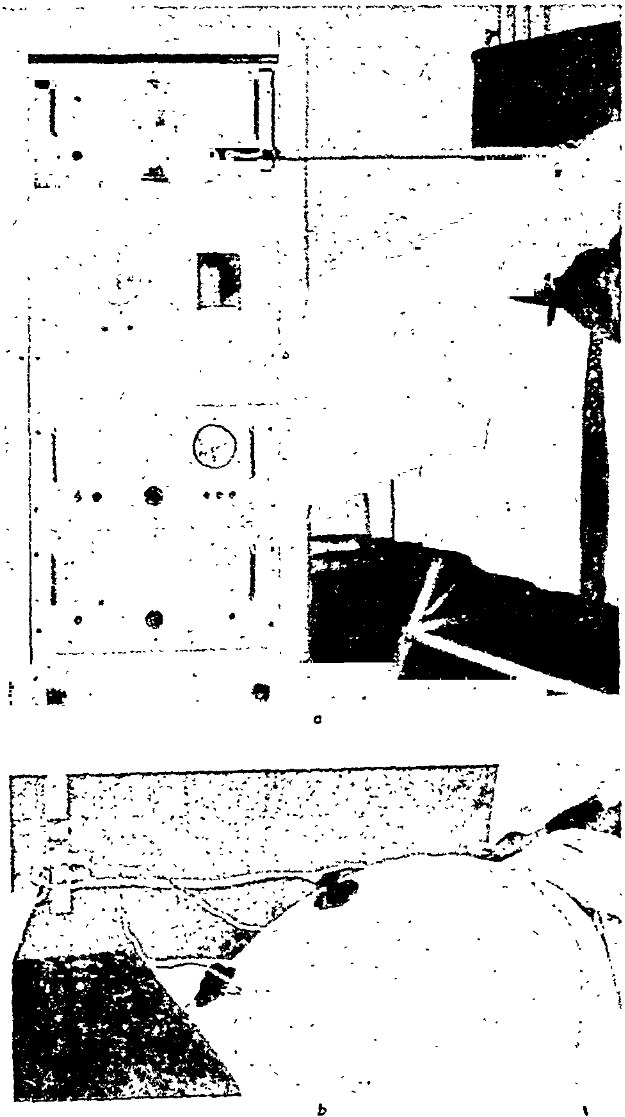

Fig. 2—Apparatus: *a*, fœtal heart 'QRS' electrocardiograph; *b*, electrodes on linea alba and iso-electric belt round waist.

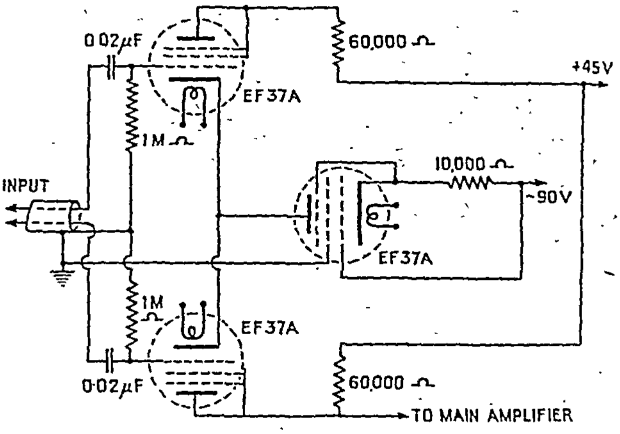

Fig. 1—Pre-amplifier circuit for fœtal electrocardiograph.

In recent years regard to the importance of early recognition of signs of fœtal distress has led to some reduction in the stillbirth-rate—e.g., by cæsarean section in the first stage of labour, by speedy forceps delivery in the second stage, and by simple methods, where they are effective, such as relieving pressure on the presenting part, sedation, and oxygen to the mother. If further improvement is to be obtained, then a more reliable method than occasional listening to the fœtal heart is necessary for the recognition of fœtal distress. Especial interest attaches to automatic recording in addition to the advantages of continuity and of convenience. It has been shown that frequent listening leads to anxiety in the mother, which reflects itself in the fœtal heart-rate as well as disturbing the mother's enjoyment and coöperation in the birth process.

The fœtal heart makes itself evident, as does the adult heart, by sound, by ballistic reaction, and by the electrocardiograph potentials. Sensitive measuring devices based on any of these effects are possibilities, and the selection of the one on which to concentrate a research programme is influenced by considerations of the extraneous disturbing effects which may lead to the production of artefacts in the recorded results, and considerations of the possibility of removing such unwanted disturbances.

Factors which disturb all recordings are maternal heart effects, movements of the mother or of the fœtus, and circulation noises and digestive noises in the patient. In the apparatus there is residual noise due to the discrete nature of valve currents and to thermal agitation, and noise which may be generated by friction or by chemical action between the patient's skin and the measuring device applied to her. Other sources of interference are extraneous room noises from people moving and talking, traffic, door and lift noises, and electrical disturbances from machinery, X rays, diathermy, and broadcasting stations, and frictional electricity from moving clothes, blankets, and trolleys.

Consideration of the practicability of eliminating unwanted effects from the recordings over long periods of time and with the minimum of inconvenience to the patient led us to concentrate on electrocardiography, although we first made preliminary tests with the other two methods to confirm that the supposed difficulties were real.

Our object was to record the heart-rate and irregularity up to and including delivery, so that, besides detecting fœtal distress, we could control the administration of sedatives, anæsthetics, and other drugs, and carefully

Reviews of Books

Contrast Psychology

A Concept of the Movements of the Human Spirit MURDO MACKENZIE, M D, M R C P, consultant physician in psychological medicine, St John's Hospital, Lewisham London Allen & Unwin 1952 Pp 305 21*s*

Dr Mackenzie looks at individual and community problems from his own highly characteristic viewpoint Briefly, he uses the term spirit to denote "the zest or enthusiasm which characterises mental activity at all levels" and believes that personality comprises two distinct components, the first being described as either Immediacy or Deliberation, the second as either Amplification or Simplification Each of these pairs is in irreconcilable contrast to its opposite number but may team up with either one of the other pair This rather rigid schema, inspired by Hegel and A N Whitehead, is applied to the discussion of the community sense of the ancient Greeks and Romans Christian medieval theology, the modern bid for Freedom (from John Locke to Stalin), and the psychology of the Unconscious (Freud, Adler, and Jung) These central chapters, which form the bulk of the book, are written in an eloquent narrative style reminiscent of Carlyle, and present familiar facts in a stimulating and original light The application of the author's cut-and-dried ideas to the consideration of clinical problems in the individual leaves the reader feeling that, somehow, human personality appears more pigeon-holed and docketed by this system of hard-and-fast contrasts than when it is viewed from the unitary standpoint—of psycho-analysis, for example Here are theories in plenty, but the facts and scientific data to confirm or disprove them are nowhere convincingly presented

Atlas of Skull Roentgenograms

BERNARD S EPSTEIN, M D, associate radiologist, Jewish Hospital of Brooklyn, New York, LEO M DAVIDOFF, M D, neurosurgeon Mount Sinai Hospital, New York City London Henry Kimpton 1953 Pp 400 110*s*

THIS book is a collection of X-ray films of the skull, with a short text preceding each section The emphasis is laid on the plain film the special investigations have been excluded It is comprehensive, and many beautiful examples and rare conditions are shown The authors' expressed intention was to keep the text as short as possible but this perhaps has been carried too far Anyone interested in so specialised a subject can be expected to know the essentials, and in many instances more detailed information would be welcome The films are reproduced as negatives, two to a page, and are up to modern American standards, but they do not all convey the very fine detail necessary for the study of skull films As with all atlases, except perhaps the geographical kind, one is left wondering for whom *it* was designed

Vitamin Digest

GUY W CLARK, technical director, Lederle Laboratories Division, American Cyanamid Co Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1953 Pp 254 47*s* 6*d*

THE aim of this book is to give a comprehensive but brief account of both the chemistry and the nutritional importance of all the known vitamins Its 17 chapters range in length from 22 pages about vitamin B_1 down to only 5 pages about *p* aminobenzoic acid After a brief account of the discovery of each vitamin the author attempts to discuss the main scientific developments in its investigation, and completes the picture with information on the allowances which are necessary for adults and children, and on the effects on the vitamin of cooking and food processing

Anyone who is familiar with the wealth of information now available on the vitamins will recognise the difficulty of the task which the author has set himself He must not only be widely read and experienced, but must be able to discriminate in deciding what material to include and what to reject The present work deserves praise at least for providing much valuable information in compact and well-connected narratives The choice of material, however, leaves many fundamental discoveries unmentioned Thus in the chapter on vitamin A no reference is made to the work on its chemical structure for which Karrer earned a Nobel award Steenbock and Black are given no credit for their classical discovery that foods are made antirachitic by ultra violet irradiation, and only one obscure reference is made to Dam's numerous recent contributions to research on vitamin E

Rheumatic Fever

Editor LEWIS THOMAS, M D Minneapolis University of Minnesota Press London Oxford University Press 1952 Pp 349 80*s*

THESE symposia, so often reported to us from the United States, are an admirable feature of American medical life in its academic reaches The local organisers usually pick the distinguished contributors, and a drug firm, or occasionally a charitable organisation (in this case the Minnesota Heart Association), pays their expenses Leading workers in the field under review summarise the position and bring their own up-to-the-minute contributions In a small subject, on which few are working, letter-writing and the reading of one or two journals may achieve the same object less pleasantly though more cheaply, but rheumatic fever demands the attention of cardiologist, pædiatrician, epidemiologist pathologist, bacteriologist, immunologist, chemist, and even surgeon All took part in this symposium, only the geneticist the public-health worker, and the student of comparative medicine seem to have missed their planes Dr Francis Schwentker's paper on the epidemiology of rheumatic fever partly makes up for their absence, but the focus generally is on tissue rather than patient This bias is partly corrected by Duckett Jones and Bland's paper on the natural history of the disease, as well as the studies of Rammelkamp, Denny, and Wannamaker on its epidemiology in the Armed Forces The twenty-odd papers were of high standard, and the discussions were generally apt and entertaining

---

Pulmonary Tuberculosis (3rd ed Edinburgh E & S Livingstone 1953 Pp 324 24*s*) —This practical and trust worthy handbook has had a stormy time since the second edition appeared in 1946 for much has happened in the tuberculosis world since then Dr R Y Keers and Dr B G Rigden have had to take their text apart and rewrite it almost completely in order to express modern opinion on the bacteriology, chemotherapy and surgery, aftercare and prevention of this much harassed disease, and even then they have had misgivings lest the whole scene might change before publication date Dr F H Young in his foreword, however, says that this new edition will enable him to recommend this little book *to* his students with even more enthusiasm

Problems of Fertility in General Practice (2nd *ed* London Cassell 1953 Pp 259 18*s* 6*d*) —The first edition of this book, by Mr John Stallworthy, Mr Kenneth Walker, Dr Joan Malleson, and Dr Margaret Hadley Jackson, appeared in 1948 and was well received Since this new edition is identical in form and virtually unaltered in content, it must be assumed that the authors have considered that none of the recent contributions to the literature are worthy of comment in a book designed primarily for general practitioners Nevertheless, it would have been well to include some later references, and to comment on recent work, even if only to indicate to the practitioner that not every contribution to this subject should be accepted uncritically The chapter on "coital problems" remains an admirable exposition of this difficult aspect of infertility, while the section on abortion is again disappointing too much space being given *to* the Rh reaction, which is not really important in connection with abortion It is satisfactory to note the references to the actual cost of hormone therapy The useful appendix now includes a reference to the work of Mann and Parsons on the fructose content of seminal fluid The comments on the nature of approved contraceptives are *more* detailed than they were and the list of Family Planning Association clinics has been brought up to date, but the appendix could have been improved by the addition of a list of the hospitals both in London and in the provinces where complete investigation of infertility cases is undertaken relate obstetric procedures, such as cæsarean section and forceps delivery, to fœtal welfare.

The results to date of our efforts to achieve this objective are published now in the belief that they may be of use to many others who are attempting the same task, and in the hope that the remaining difficulties enumerated may be solved or turned to clinically good use. They are grouped into a brief description of the apparatus (adequate for those working on this side of the problem), a description of the results obtained, a statement of the remaining difficulties, and finally some suggestions arising from our work.

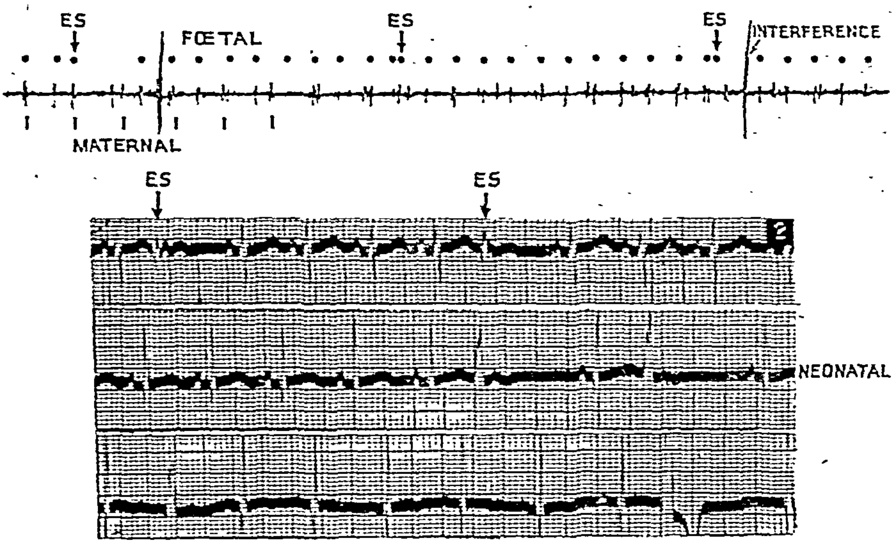

Fig. 6—Fœtal electrocardiogram showing congenital extrasystoles, with confirmation in recording made after birth.

APPARATUS

The recorder used for the investigations comprised a direct writing electrocardiograph of conventional design, preceded by a balanced preamplifier operated from batteries and arranged as shown in the circuit in fig. 1. The complete unit had an equivalent noise level of 3 µV when operating from a source impedance of 20,000 ohms. The frequency response was adjusted to cut off below 30 c.p.s. and above 100 c.p.s.

Connections to the patient were made by fine-silver electrodes placed on skin which had been cleaned and moistened with saline solution. The most satisfactory size was found to be 1¼ in. diameter.

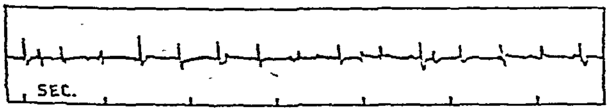

Fig. 3—Fœtal electrocardiogram: electrode of fine silver wire passed into amniotic cavity through polythene catheter during surgical induction of labour at full term.

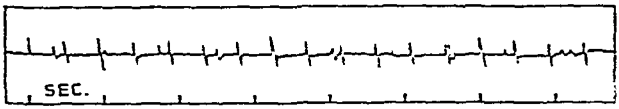

Fig. 5—Fœtal electrocardiogram: abdominal electrodes, fœtus at 20 weeks' gestation.

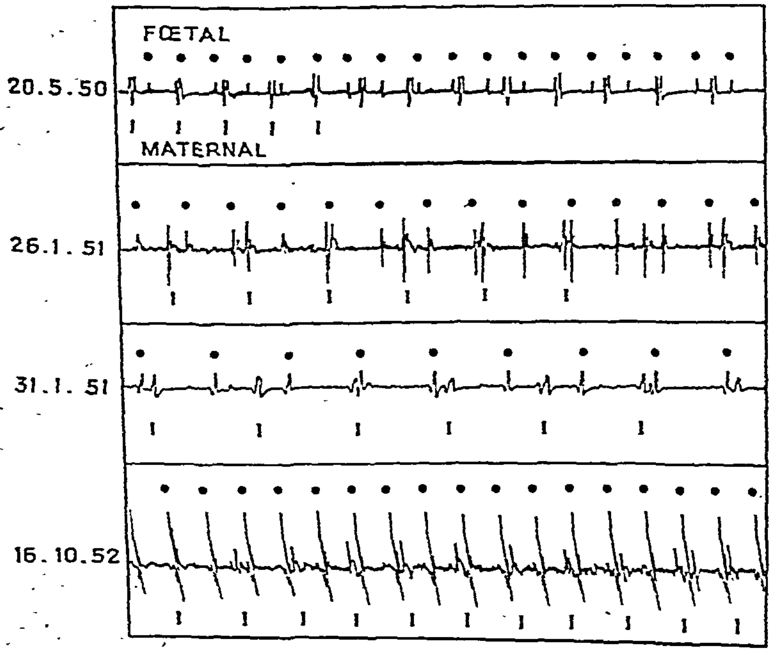

Fig. 4—Typical electrocardiograms made between 1950 and present date.

The preamplifier was of the balanced-input type, being sensitive to differences in potential between the two electrodes and very much less sensitive to potentials between either electrode and earth.

The most important improvement made in electrode connections was the addition of a metal braid belt placed round the mother's waist half-way between the xiphoid process and the fundus uteri. It was connected to earth. It had the effect of making the abdominal skin nearly iso-electric for maternal heart potentials. In men and non-pregnant women the effect of the belt was practically complete, but in pregnant patients there was a considerable difference between cases, a difference which may perhaps be related to uterine blood-supply or to placental position. The electrocardiograph is shown in fig. 2a, and the electrodes (covered with black cloth to make them clear in the photograph) in fig. 2b.

The electrocardiograph also included an integrator for registering fœtal heart-rate, and a neon tube which flashed synchronously with the fœtal heart-beats, and these worked well in cases where the fœtal-heart recordings were dominant over unwanted signals.

RESULTS

More than 100 patients have had fœtal electrocardiographic recordings; the fœtal Q R S complex was recognised in all but 2, and in these the fœtus was dead. In only about 20%, however, was the fœtal Q R S of greater amplitude than the maternal; in about a further 20% it was equal; and in the rest it was smaller but always recognisable.

The recordings confirmed Bell's (1938) suggestion that the linea alba was a favourable site for the electrodes. We placed one just above the umbilicus for vertex presentations, or at the fundus

THE LANCET

LONDON SATURDAY, JUNE 6, 1953

Bed Rest in Tuberculosis

REST in bed is the least disputed treatment of pulmonary tuberculosis But this simple measure was not always popular In the time of HIPPOCRATES it was recommended for treating hæmoptysis, and it was expected to cure the patient if he was not too emaciated Other allusions to rest are, however, few in ancient medical literature The great SYDENHAM advised horse-riding as a specific even " after wasting, night sweats and colliquative diarrhœa have signified the approach of death provided only that the journeys are long enough and the beds at night well aired " Subsequently physicians prescribed such exercise only for the more robust, but it was not until late in the 19th century that strict rest in bed began to be valued In 1863 JOHN HILTON in his book *On Rest and Pain*, recorded that a young girl with tuberculosis of the hip and lungs ceased to cough and improved in general health while remaining in bed with the hip splinted It seems that the importance of his observation was not generally appreciated, and in 1873 EDWARD TRUDEAU, when told that he had phthisis, followed the advice of his doctor and went to the Adirondacks to live out of doors and ride When this failed he rested, and the sanatorium he founded at Saranac is a memorial to the efficacy of rest in pulmonary tuberculosis

At Trudeau Sanatorium MITCHELL [1] has studied the results of bed rest in " minimal " pulmonary disease by analysing 589 cases of limited uncavitated tuberculosis which were treated between 1927 and 1946 As the mortality-rate was low—5% in twenty years—he used the relapse-rate to measure the effect of treatment, which basically consisted in rest in bed for all but three or four hours a day The duration of rest appeared to have no effect on the frequency of relapse Thus, of 310 patients who were in bed for only one or two months, 22 3% relapsed within five years, while of 109 who had six or more months in bed 22% relapsed As would be expected, the prognosis was significantly affected by the extent of the disease, but this could not explain the lack of correlation between duration of rest and relapse, for it did not appear to have been an important factor in determining the duration of rest Moreover, those who spent the shortest time in the sanatorium seemed to have done no worse than those who spent the longest MITCHELL then investigated the late results in patients with pleural effusions [2] The relapse-rate within five years of discharge was found to be influenced by the presence of minimal pulmonary disease and by its extent But, once more, the duration of bed rest or stay in the sanatorium had no obvious effect The interpretation of such retrospective investigations is, as MITCHELL emphasises, very difficult, and he wisely presents the facts without drawing conclusions The absence of a clear relationship between duration of treatment and liability to relapse might well be due to the many variables that cannot be measured For instance, it is impossible to evaluate or record all the factors that make the physician decide to start getting a patient up, and radiographic appearances and the bacterial content of the sputum are very crude indices of the patient's state Moreover, the patient's fate after discharge is probably determined much more by himself and his environment than by the treatment he has received in hospital

CHRISTOPHER BENNET [3] wrote in 1654

> " The manner of lying at Night and sleeping is by no means to be neglected Lying on the Left side is most hurtful to those who have the Lungs burdened by a thin Suffusion, and they who lie on their Backs are most incommoded if they are offended by a Distillation "

It seems that, although there may not nowadays be a " thin suffusion," lying on the left side can be harmful for patients with a tuberculous cavity on the right HELM [4] investigated the sleeping habits of a group of patients with unilateral cavities and found that spread to the other lung was commoner in those who habitually slept on the healthy side Sleeping on the side is thought to promote aspiration into the lower lung of infected material from a cavity in the upper. Such aspiration spread is probably a common mode of progression, and recently SCHWARTZ [5] has claimed that another common route is by the bronchial lymphatics The infection passes along the chain of lymph-nodes and may reach the opposite side by the mediastinal lymphatic communications, segmental tuberculous pneumonia follows from rupture of a node into the bronchus and aspiration of the caseous contents It seems that posture in bed may also affect the size of cavities Over thirty-five years ago WEBB et al [6] [7] in the U S A advised that patients should be nursed on their affected side, and recorded many good results from this simple postural treatment Little more was heard of it until 1948, when DILLWYN THOMAS [8] reported that it was useful for some patients with large cavities who were being prepared for thoracoplasty Since then several others [9–12] have written favourably of this treatment, which has been variously termed reversed postural drainage, postural retention, or postural reduction The benefit from it has been ascribed to decrease in the volume of the dependent lung and changes in its blood-flow, lessened respiratory movement, and retention of secretions within the cavities or (by others) improved drainage of cavities

BENNET sought to explain his observations in the idiom of his time by means of " distillations," " fizzy serum," and " acrid humours " In his day he can have seen few cures, and he himself died of consumption a year after his book was published It is interesting to recall his long-forgotten advice, for the manner of lying is by no means neglected in the modern treatment of pulmonary tuberculosis by rest in bed for breech cases, and the other close to the symphysis pubis (fig. 2b). Vaginal and rectal electrodes cause discomfort of the perineum with consequent increase in perineal action potentials which disturbed the recordings. Œsophageal electrodes were not tried. In one case a fine silver-wire electrode was passed into the amniotic sac through a 'Polythene' catheter which had been previously positioned at a high artificial rupture of membranes, and the result was superior to abdominal recording by a factor of five times in fœtal-heart potential to all unwanted potentials (fig. 3).

Four typical recordings from the abdominal surface taken between May, 1950, and the present date are shown in fig. 4. Fig. 5 shows a similar recording from a patient only 20 weeks pregnant.

The remaining difficulties are to eliminate the maternal heart-beat potential from the fœtal record and to make the apparatus less responsive to action potentials from voluntary muscle. An additional amplifier working in antiphase to the fœtal electrocardiograph and collecting potentials from the maternal heart only would make it possible to eliminate the maternal trace from the record, but the method involves applying more electrodes to the mother, and the process becomes cumbersome. Interference from voluntary-muscle action potentials may be further reduced by a sharper frequency cut-off to the amplifier top frequency characteristic.

The work has shown that the apparatus may give information on two subjects other than that for which it was originally designed: (1) the amplitude and distribution of maternal heart potentials upon the abdominal surface below the iso-electric belt may be correlated with records taken in cases of retained placenta or cæsarian section to give some indication of the position of the placenta; and (2) the presence of action potentials on the recordings gives immediate indication of the patient's ability to relax between contractions, and can be used, if coupled to a loud-speaker, to obtain the patient's coöperation.

The variation of fœtal heart-rate during contractions, during administration of oxygen or of sedatives to the mother, or when the mother is placed in an attitude which removes pressure from the presenting part, may give information leading to a classification of fœtal distress which will give a rational basis for treatment.

Fig. 6 shows the fœtal and neonatal electrocardiograms of a child with congenital extrasystoles.

Professor Nixon, director of the obstetric unit, proposed this investigation and has given much practical encouragement. The work was made possible through the generosity of the Board of Governors of University College Hospital.

ADDENDUM

Since this article was written, the author has had the help of Messrs. Muirhead Ltd., in making energy-frequency analyses of the QRS complex of adult, newborn, and fœtal hearts. The conclusions were that:

(1) The energy is widely distributed in frequency but is maximal in the normal adult between the frequences 10 and 20 c.p.s.

(2) In both the newborn and the *fœtus* the energy is greatest between 20 and 40 c.p.s.

Furthermore it has been shown that if the frequency response of the recording apparatus is limited to 40 c.p.s., the interfering effects from gross muscle action potentials are substantially reduced.

ERYTHEMA MULTIFORME EXUDATIVUM MAJOR

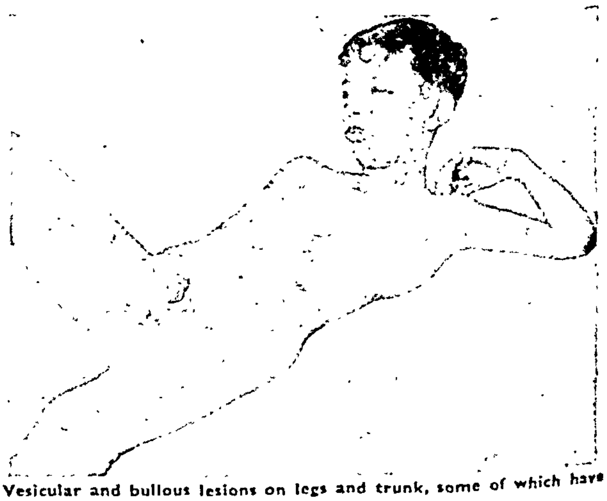
(STEVENS-JOHNSON SYNDROME)

D. M. DAVIES
M.R.C.S.
MEDICAL REGISTRAR, BOLINGBROKE HOSPITAL, LONDON

ERYTHEMA multiforme exudativum major (Thomas 1950, Ashby and Lazar 1951), the so-called Stevens-Johnson syndrome, is a familar disease to dermatologists and ophthalmologists, but it is not so well known to others; nor does it receive the attention it deserves in general medical textbooks.

In the past the subject has been confused, for several diseases, having important features in common, have been described as separate entities. More recently, however, it has become customary to regard these as different forms of one disease (Ashby and Lazar 1951, *Journal of the American Medical Association* 1951, Billow and Lowen 1952). Thus, Hebra (1860) first described "erythema multiforme exsudativum" as an illness characterised by pleomorphic lesions confined to the skin without systemic disturbance; though later (Hebra 1866) he described a case in which the typical rash was associated with pneumonia. Later, others described cases in which the pleomorphic skin rash was accompanied by a more severe illness, with ulceration of the eyes, mouth, and genitalia, and, in some cases, urethritis and an abacterial pneumonia. Some of these cases were described under such names as "ectodermosis erosiva pluriorficialis" (Rendu 1916, Klauder 1937), "dermato-stomatitis" (Baader 1925), "the new eruptive fever" (Stevens and Johnson 1922), "the triple complex" (Behcet 1940), and "the mucosal-respiratory syndrome" (Stanyon and Warner 1945). Recently it has been argued that all these diseases should be included within Hebra's original erythema multiforme exudativum (*Journal of the American Medical Association* 1951, Billow and Lowen 1952); while others (Thomas 1950, Ashby and Lazar 1951) have subdivided the disease into minor and major forms, the minor form corresponding to Hebra's original description, and the major form to the type of illness described by Stevens and Johnson and others.

In the minor form the skin rash may show macules, papules, vesicles, or bullæ, or a mixture of two or more. The lesions, which are usually deep red at first and later purplish, are typically distributed on the sides of the face and neck, and on the extensor surfaces of the limbs. There is little systemic disturbance. The major form has



Vesicular and bullous lesions on legs and trunk, some of which have broken down

Are you

...taking your iron regularly?

It is generally agreed in Medical circles that a sufficient intake of iron is of paramount importance during pregnancy

To prescribe iron, in some form, to expectant and nursing mothers is a simple procedure, but can you always be sure that it will be taken?

How many times do patients confess, under gentle pressure from their doctor or nurse, that they somehow forgot to take their tablets after breakfast or lunch?

You can ensure that your patients are receiving an adequate dosage of iron if you prescribe PRENATALAC for them This food, prepared specially for expectant and nursing mothers, contains 50 mgms of Fe et Amm Cit to the ounce, thus ensuring an adequate intake

HEMOLAC, containing 25 mgms of the same iron salt per ounce, is made especially for microcytic anaemia of infancy

COW & GATE MILK FOODS

GUILDFORD SURREY

5020

a prodromal period of about a week during which such symptoms as general malaise, cough, vomiting, and epistaxis may appear. These symptoms are followed by the rash which may involve the eyes, mouth, and genitalia, as well as the skin of the face, trunk, and limbs. The scalp is almost invariably spared. Urethritis and pneumonia may also be present. The illness may last from two weeks to two months and usually ends in complete recovery, though it is sometimes fatal. Corneal scarring may produce blindness.

The cause is unknown. In some cases it has been associated with underlying visceral disease; in others, allergy to foods, bacterial toxins, or drugs—especially sulphonamides—has been suggested as a cause; while some writers have suggested that a virus is responsible (Finland et al. 1948, Anderson et al. 1949).

As might be expected, there is no general agreement on treatment. Success has been claimed for sulphonamides and penicillin (Wright et al. 1947), and for aureomycin (Church 1950, Lynas 1950). Others deny the specificity of these drugs, but agree that one or other should be given to combat secondary infection, especially of the eyes and lungs (Billow and Lowen 1952). Cortisone has been tried recently with encouraging results (Fishman 1951); and adrenocorticotropic hormone (A.C.T.H.) is sometimes very effective (Caldwell 1953).

CASE-RECORD

This case illustrates unusually clearly the main features of erythema multiforme exudativum major.

A boy, aged 10, was admitted to the Bolingbroke Hospital on Aug. 19, 1952. On Aug. 9 he had an attack of migraine, to which he was subject. The headache gradually subsided the next day, but the day after that he had a cough, which gradually became worse in the next few days, and he became listless and feverish. On Aug. 15 he lost his appetite, vomited several times, and slept poorly. Next day his cough was very much worse, and he became flushed and irritable. His mouth became sore, his lips swollen, and his eyes red and watery. One or two irritating spots appeared on the trunk and limbs. Treatment with sulphonamides was begun, but that night his condition deteriorated and he became delirious. There was quite severe bleeding from the mouth, followed by four severe epistaxes. The spots became more profuse and the eyes purulent. On Aug. 18, the day before his admission, sulphonamides were stopped and penicillin by injection was started.

When he came to hospital, he was profoundly ill, with a temperature of 103°F, a pulse-rate of 130 per minute, and a respiratory rate of 36 per minute. The lips were swollen, ulcerated, and encrusted with dried blood. The gums, tongue, and buccal mucosa were red, ulcerated, and bleeding. There were several small vesicles on the conjunctivæ, which were inflamed and purulent; the corneæ were not affected. The rash consisted of vesicles and bullæ which had broken down in places, leaving ulcers set on purplish patches of skin. On the upper limbs the rash involved mainly the extensor aspects of the arms, forearms, and hands. On the lower limbs the lesions were most numerous on the front and medial surfaces of the thighs (see figure), the medial surfaces of the legs, and the dorsal surfaces of the feet. All surfaces of the trunk were involved; but the axillæ, palms, and soles escaped. The scrotum, prepuce, glans penis, and meatus were ulcerated, and there was a scanty urethral discharge. In the chest, there were scattered rhonchi in all areas, with fine crepitations at the right base.

Investigations.—A radiograph of the chest showed patchy consolidation of the right lower perihilar region. Hb 92%; white-cell count 10,300 per c.mm. (polymorphs 71%, lymphocytes 15%, monocytes 12%, and plasma cells 2%); erythrocyte-sedimentation rate 56 mm. in 1st hour (Westergren). Blood-culture sterile. Examination of the contents of the bullæ showed a few pus cells, but the culture was sterile. Swabs from the nose and throat showed no significant pathogens. The urine showed no abnormality, the urethral discharge being short-lived.

Progress and Treatment.—The morning after admission the temperature fell to normal, but rose in the evening to 104·2°F. It gradually subsided during the next five days, and, apart from one rise to 99·6°F on Aug. 30, it then remained normal. Treatment with penicillin was continued after admission, and chloramphenicol was also given. On Aug. 21, though his temperature had fallen, he appeared so ill that sulphadiazine (total dosage 28 g.) and aureomycin (total dosage 24 g.) were substituted, but they had no dramatic effect. On Aug. 28 the condition of his eyes gave rise to anxiety, and cortisone eye-drops (6·25 mg. to 1 ml. of saline solution) were instilled for seven days. His condition then gradually improved, and he was discharged on Sept. 18.

SUMMARY

A boy, aged 10, showed the main features of Stevens-Johnson syndrome (erythema multiforme exudativum major) unusually clearly.

He was treated successively with sulphonamides, penicillin, chloramphenicol, and sulphadiazine and aureomycin. Cortisone eye-drops were also given. He recovered completely.

I am indebted to Dr. R. Ewing Rodgers for permission to publish this case, and to Mr. D. M. Thomas for the photograph.

STEVENS-JOHNSON SYNDROME TREATED WITH A.C.T.H

W. G. D. CALDWELL
M.A., M.D. Dubl., M.R.C.P.I.

SENIOR MEDICAL REGISTRAR, THE ROYAL SOUTH HANTS HOSPITAL, SOUTHAMPTON

Stevens-Johnson syndrome is thought to be a variety of erythema multiforme exudativum. Robinson (1951) includes this disease, along with erythema multiforme, ectodermosis erosiva pluriorificalis, Behcet's disease, and Reiter's disease, in the term "ocular mucous-membrane syndrome." It was first described as a separate entity by Stevens and Johnson (1922).

The syndrome consists of a skin rash associated with lesions of the mucous membranes (such as stomatitis, vaginitis, or urethritis), the eye, and the respiratory tract. The skin lesions may be macular, papular, iris-type, vesicular, or bullous. The ocular lesions consist of conjunctivitis, iritis, or keratitis. Corneal ulceration may occur and lead to total blindness. In the respiratory tract there may be an acute bronchitis or pneumonitis, but this system is not always attacked (Finland et al. 1948). The onset is usually abrupt and systemic disturbance may be considerable. Untreated, the disease usually runs a course of about three weeks, ending in recovery, though it is occasionally fatal. The chief danger, however, is damage to the eyes.

Treatment of the disease has varied. Only fair results have been claimed with sulphonamides (Givner and Ageloff 1941, Erger 1944, Kove 1945, Wright et al. 1947, Wentz and Seiple 1947, Thomas 1950) and *penicillin* (Kove 1945, Wright et al. 1947, Thomas 1950). The course of the disease has hardly been shortened by these drugs, though complications may have been controlled.

LONDON SATURDAY, JUNE 6, 1953

Bed Rest in Tuberculosis

REST in bed is the least disputed treatment of pulmonary tuberculosis But this simple measure was not always popular In the time of HIPPOCRATES it was recommended for treating hæmoptysis, and it was expected to cure the patient if he was not too emaciated Other allusions to rest are, however, few in ancient medical literature The great SYDENHAM advised horse-riding as a specific even " after wasting, night sweats and colliquative diarrhœa have signified the approach of death provided only that the journeys are long enough and the beds at night well aired " Subsequently physicians prescribed such exercise only for the more robust, but it was not until late in the 19th century that strict rest in bed began to be valued In 1863 JOHN HILTON in his book *On Rest and Pain*, recorded that a young girl with tuberculosis of the hip and lungs ceased to cough and improved in general health while remaining in bed with the hip splinted It seems that the importance of his observation was not generally appreciated, and in 1873 EDWARD TRUDEAU, when told that he had phthisis, followed the advice of his doctor and went to the Adirondacks to live out of doors and ride When this failed he rested, and the sanatorium he founded at Saranac is a memorial to the efficacy of rest in pulmonary tuberculosis

At Trudeau Sanatorium MITCHELL [1] has studied the results of bed rest in " minimal " pulmonary disease by analysing 589 cases of limited uncavitated tuberculosis which were treated between 1927 and 1946 As the mortality-rate was low—5% in twenty years—he used the relapse-rate to measure the effect of treatment, which basically consisted in rest in bed for all but three or four hours a day The duration of rest appeared to have no effect on the frequency of relapse Thus, of 310 patients who were in bed for only one or two months, 22 3% relapsed within five years, while of 109 who had six or more months in bed 22% relapsed As would be expected, the prognosis was significantly affected by the extent of the disease, but this could not explain the lack of correlation between duration of rest and relapse, for it did not appear to have been an important factor in determining the duration of rest Moreover, those who spent the shortest time in the sanatorium seemed to have done no worse than those who spent the longest MITCHELL then investigated the late results in patients with pleural effusions [2] The relapse-rate within five years of discharge was found to be influenced by the presence of minimal pulmonary disease and by its extent But, once more, the duration of bed rest or stay in the sanatorium had no obvious effect The interpretation of such retrospective investigations is, as MITCHELL emphasises, very difficult, and he wisely presents the facts without drawing conclusions The absence of a clear relationship between duration of treatment and liability to relapse might well be due to the many variables that cannot be measured For instance, it is impossible to evaluate or record all the factors that make the physician decide to start getting a patient up, and radiographic appearances and the bacterial content of the sputum are very crude indices of the patient's state Moreover, the patient's fate after discharge is probably determined much more by himself and his environment than by the treatment he has received in hospital

CHRISTOPHER BENNET [3] wrote in 1654

> " The manner of lying at Night and sleeping is by no means to be neglected Lying on the Left side is most hurtful to those who have the Lungs burdened by a thin Suffusion, and they who lie on their Backs are most incommoded if they are offended by a Distillation "

It seems that, although there may not nowadays be a " thin suffusion," lying on the left side can be harmful for patients with a tuberculous cavity on the right HELM [4] investigated the sleeping habits of a group of patients with unilateral cavities and found that spread to the other lung was commoner in those who habitually slept on the healthy side Sleeping on the side is thought to promote aspiration into the lower lung of infected material from a cavity in the upper Such aspiration spread is probably a common mode of progression, and recently SCHWARTZ [5] has claimed that another common route is by the bronchial lymphatics The infection passes along the chain of lymph-nodes and may reach the opposite side by the mediastinal lymphatic communications, segmental tuberculous pneumonia follows from rupture of a node into the bronchus and aspiration of the caseous contents It seems that posture in bed may also affect the size of cavities Over thirty-five years ago WEBB et al [6] [7] in the U S A advised that patients should be nursed on their affected side, and recorded many good results from this simple postural treatment Little more was heard of it until 1948, when DILLWYN THOMAS [8] reported that it was useful for some patients with large cavities who were being prepared for thoracoplasty Since then several others [9–12] have written favourably of this treatment, which has been variously termed reversed postural drainage, postural retention, or postural reduction The benefit from it has been ascribed to decrease in the volume of the dependent lung and changes in its blood-flow, lessened respiratory movement, and retention of secretions within the cavities or (by others) improved drainage of cavities

BENNET sought to explain his observations in the idiom of his time by means of " distillations," " fizzy serum," and " acrid humours " In his day he can have seen few cures, and he himself died of consumption a year after his book was published It is interesting to recall his long-forgotten advice, for the manner of lying is by no means neglected in the modern treatment of pulmonary tuberculosis by rest in bed

Recent results with aureomycin (Church 1950, Lynas 1950, Khayat and Jacoby 1950, Robinson 1951) have been more hopeful, and the course of the disease has apparently been shortened. In a case reported by Orme (1952), neither penicillin nor aureomycin appeared to have any effect, and the patient died.

In my view many features of the syndrome suggest an allergic basis, and in the case reported here it was decided to try the effect of adrenocorticotropic hormone (A.C.T.H.). So far only four previous reports of the use of A.C.T.H in this condition have been noted (Wammock et al. 1951, Agostas et al. 1951, Orme 1952, Steigman and Kelly 1952). It seems important to record the following case because of the dramatic response to A.C.T.H., and because the rarity of the disease makes it unlikely that a large series of cases can be studied in one centre.

CASE-RECORD

An obese woman, aged 54, was admitted to hospital on Oct. 17, 1951. She was first seen in the medical outpatient department one month previously, when she was found to be suffering from myxœdema, for which thyroid was given. One week before admission she developed dysuria and frequency which was treated with sulphadimidine and potassium citrate for four days. Both drugs were then stopped because tonsillitis, stomatitis, and an extensive generalised rash developed on the fourth day of treatment. Anti-histamine cream was prescribed before admission, but it did not seem to help the condition. Bilateral conjunctivitis was noted twenty-four hours before admission. There was no history of previous allergy or the taking of any drug before the onset of the dysuria, apart from small doses of thyroid extract. She had suffered from rheumatic fever in childhood. There was no significant family history.

On admission she was very ill with an axillary temperature of 101°F and a pulse-rate of 100 per minute. The stomatitis was so severe that she had great difficulty in swallowing and she had taken no fluids for at least twelve hours. There was swelling and blistering of the lips and buccal mucosa, and several sloughing erosions on the buccal mucosa where large vesicles had broken down. She had definite halitosis.

The rash covered the face, the upper arms, the forearms, the dorsum of both hands, the front of both lower legs, and the buttocks. It consisted of macules, papules, and vesicles: the macules were purplish-red, and over the forearms and legs they had the typical iris configuration seen in erythema multiforme. There were papules and vesicles on both labia majora and labia minora. Several of the vesicles had ruptured leaving sloughing erosions. The inflammation had extended to the urethra, thus accounting for the dysuria. The palpebral and scleral conjunctivæ on both sides were very injected. A diagnosis of Stevens-Johnson syndrome was made.

She also had aortic stenosis, with grade II apical and aortic systolic murmurs. The rhythm was regular and the blood-pressure was 100/70 mm. Hg. The electrocardiographic tracings were normal. No abnormalities were found in the respiratory system or abdomen, and a radiograph of the chest was normal. The lymphatic glands and nervous system were also normal.

Investigations.—Hb 92%; white-cell count showed a mild polymorphonuclear leucocytosis (87% polymorphs in a total count of 11,100); W.R. negative. Apart from a small amount of protein present on admission, which cleared completely within four days, the urine was normal.

Progress and Treatment.—On the day of admission 0·5 ml. of 1 in 1000 adrenaline was given by injection with a little relief, and she was able to swallow slightly more easily. This was followed by 5 ml. (50 mg.) of 'Benadryl' intravenously. The dysphagia recurred, and twenty-four hours later these drugs were repeated but with little benefit. There was no improvement in the skin condition.

Two days after admission, in view of the lack of response to the anti-histamines, it was decided to try A.C.T.H. She received 25 mg. intramuscularly every six hours for four days. The dose was reduced to 20 mg. eight-hourly for a further three days and on the eighth day 10 mg. was given eight-hourly. The drug was then stopped. Improvement was noticeable within twelve hours. After twenty-four hours swallowing was easier, but the patient had a sharp attack of diarrhœa and vomiting which cleared up in twelve hours. After three days on A.C.T.H. improvement was considerable; swallowing was normal, the rash was rapidly fading, the erosions in the mouth and vulva were healing, and dysuria had ceased. Conjunctivitis was still present but minimal. Ten days after admission tests of sensitivity to sulphadimidine were carried out, both as a patch test and intradermally. Both tests were negative.

The patient was discharged twelve days after admission, when the rash had almost disappeared. Three weeks later no signs of the disease remained.

DISCUSSION

The cause of this disease is still obscure. Stevens and Johnson (1922) thought that infective factors were important, and a virus infection has been suggested (Patz 1947, Finland et al. 1948, Anderson et al. 1949). Klauder (1937) and Fitzgerald (1947) pointed out the resemblance between this disease and human foot-and-mouth disease. There is justification therefore in the use of aureomycin. But the negative pathological findings emphasised by many authors (Murphy 1944, Erger 1944, Khayat and Jacoby 1950, Thomas 1950, Wammock et al. 1951) are more in favour of an allergic origin. Drug allergy has been noted as a cause, and cases described by Greenberg and Messer (1943) and Dardinski (1945) ended fatally after sulphadiazine therapy.

Sulphadimidine was not used in the case described here until after the onset of dysuria, which was taken as the first sign of the disease. The beneficial effects of A.C.T.H. in certain types of allergy are well known, and have been recently stressed by Simpson (1952), and Pickering (1952), and it was therefore decided to use A.C.T.H. Although the patient was very ill on admission, she had made an impressive recovery after only three days' treatment, and she was completely cured after ten days on A.C.T.H. The effect was so rapid that dangerous complications had no chance to develop; this applies especially to affections of the eye. There has been no recurrence so far. Recurrences have been reported (Thomas 1950, Robinson 1951, Orme 1952), and they are thought to be a feature of the disease. The few cases of Stevens-Johnson syndrome in which the use of A.C.T.H. has been reported have all responded favourably. The evidence seems to justify the trial of A.C.T.H. in more cases of this syndrome.

SUMMARY

Stevens-Johnson syndrome in a woman of 54 responded dramatically to A.C.T.H. The use of A.C.T.H. in more cases of this syndrome would give a clearer picture of its value. The dramatic response supports the suggestion that this is an allergic condition.

My thanks are due to Dr. Kenneth Robertson for permission to publish this case and for many helpful suggestions.

Treatment of Hepatic Coma

In hepatic disease coma is a serious complication associated with a high mortality Fortunately this complication is uncommon, but because of its very uncommonness the value of any new form of treatment cannot easily be assessed Furthermore, until the cause of the coma is better understood, treatment will continue to be empirical

In some patients with severe hepatic disease coma may be precipitated by therapeutically induced changes in their blood electrolytes Large doses of glucose intravenously may result in severe hypopotassæmia, and severe salt restriction, especially if associated with paracentesis and administration of mercury diuretics, may lead to the low-salt syndrome With either of these states, there may be drowsiness and stupor, which is rapidly dispelled when the electrolyte imbalance is corrected and some of the successes claimed for various therapeutic regimes are probably attributable to this mechanism The prognosis also depends partly on the underlying hepatic lesion Coma supervening, for example in a case of Laennec's cirrhosis almost invariably heralds the closing stages of the disease, whereas recovery from coma associated with liver-cell necrosis is by no means rare The high mortality with coma in Laennec's cirrhosis is illustrated by KARL and his colleagues [1] Of their series of 58 patients, all but 1 died, and as two-thirds of the patients were in hospital when coma developed, the high mortality cannot be attributed to lack of opportunity for proper treatment KARL et al rely on tube feeding with an adequate high-protein, low-salt diet, with which intravenous infusion of glucose should be unnecessary Vitamin supplements are also recommended together with crude liver intravenously There is nothing really new in this treatment, and no reason to expect that it will yield significantly better results than its predecessors In the treatment of coma associated with acute hepatic necrosis the situation is somewhat different LATNER [2] has done well to emphasise that most patients can recover from this condition, owing to the survival of considerable numbers of liver cells and their extraordinary regenerative capacity In Laennec's cirrhosis, even where the patient is comatose, necrosis of parenchymal cells is usually insignificant but their impaired capacity for regeneration is well established In acute necrosis the failure of hepatic function that manifests itself in coma is presumably caused by some acute noxa that does not persist, with the removal or neutralisation of this agent the surviving liver cells re-establish adequate hepatic function In Laennec's cirrhosis however coma arises in the presence of what appears to be a numerically adequate number of liver cells, although in some such cases a hepatotoxin may be incriminated, usually the deterioration into coma is gradual and not attributable to any particular adverse event The production of hepatic coma in dogs, by gradually increasing hepatic ischæmia,[3] raises the possibility that in the cirrhotic liver decreasing intrahepatic circulation is similarly responsible for the loss of hepatic function here the ischæmia is progressive and irreversible, and the lack of response to treatment may thus be understandable

A comparison of LATNER's results in cases of "acute yellow atrophy" with those of KARL et al makes clear this distinction Of LATNER's 5 cases 4 recovered completely, the 5th regained consciousness but died from intercurrent cellulitis In the series of KARL et al, on the other hand, of 58 patients only 1 survived The only noteworthy difference between the therapeutic regimes in these two series is the administration by LATNER of tocopherol 300 mg intramuscularly each day This was given mainly because of its action in preventing dietary liver necrosis in rats, and it is extremely unlikely to account for the great contrast in the results Dr WALSHE last week described a more promising method of treating the cirrhotic patient in coma [4] Earlier,[5] as a result of paper-chromatographic studies of blood, urine, and cerebrospinal fluid (C S F) of patients in this state, he had obtained evidence of profound disturbance of amino acid metabolism, the most striking change was an increase of glutamine in the C S F, which was sometimes accompanied by an increase of glutamic acid On the basis of these findings, WALSHE suggested tentatively "that changes in the amino-acid pattern of the body fluids are capable of producing varying neurological syndromes," including that of hepatic coma We[6] remarked that "it is difficult to understand why a moderate increase" in the concentration of glutamine and glutamic acid in plasma and C S F "should so profoundly disturb the cerebral functions" It would now appear that the metabolic fault is not an excess, but rather a deficiency, of glutamic acid This substance is necessary for removing the highly toxic ammonium radicle, produced as a normal cerebral katabolite, which combines with glutamic acid to form the amide glutamine WALSHE has obtained striking results by giving large doses of sodium glutamate intravenously

WALSHE's findings of increased glutamine, and occasionally of increased glutamic acid, in the C S F in cases of hepatic coma, could, however, be interpreted as evidence, not of disturbed metabolism of amino-acids, but of increased cerebral ammonia formation This is further supported by the finding in hepatectomised dogs of a fivefold increase of glutamine among the free amino acids of the brain [7] If this interpretation is correct we are still far from comprehending the mechanism by which hepatic insufficiency affects cerebral metabolism, but it would enable us to understand the beneficial effect of glutamic acid

The Nurse's Responsibility

WHAT with techniques multiplying and housemen scarce it is becoming harder and harder to get through the daily work of the wards in the twenty four hours supplied by the solar system One solution of such problems is to depute the work to other people, and the doctor giving, say, a course of intravenous injections must often be tempted to say to a bright and handy sister "You could do these just as well as I can suppose you take them over If she is young and fired by the opportunity she may agree and in most cases all will go well she enjoys gaining an extra skill the doctor is relieved of a tie,

THE LANCET

LONDON: SATURDAY, JAN. 10, 1953

Poliomyelitis

In 1947 poliomyelitis appeared in this country for the first time on a large scale, with 7766 notified cases and 707 deaths in England and Wales. Since then the annual incidence and deaths have been much higher than before the late war, and in 1949 and 1950 they were about the same as in 1947. Intensive research into poliomyelitis has been proceeding for many years in America, where vast experience of epidemics and vast resources devoted to their study have yielded most of our knowledge of the virology, pathology, and treatment of the disease. One of the latest triumphs of American workers has been to grow the virus by means of tissue culture.[1] This technique may soon be adapted as a relatively cheap laboratory method of diagnosis; and it may lead in due course to an attenuated-virus vaccine for active immunisation. American workers have also shown[2] that in epidemics injection of gamma-globulin may help to prevent poliomyelitis, and that if it has been injected in the week before the onset of the disease it may modify the paralysis. In Britain RITCHIE RUSSELL[3,4] made a valuable contribution by showing that fatiguing physical activity in the preparalytic stage, and especially after the onset of meningeal signs, was definitely related to the severity of the ensuing paralysis. Now complete rest is enforced whenever the preparalytic stage is diagnosed or suspected. In a brief illustrated monograph[5] RITCHIE RUSSELL outlines his views on the nature of the disease, its clinical features, predisposing factors, the management of spinal, bulbar, and respiratory involvements, and reablement. On some of these aspects there are considerable differences of opinion among physicians, orthopædic surgeons, specialists in physical medicine, and physiotherapists, which lead to confusion in the management of patients, particularly during reablement.

The early stage of meningeal symptoms is critical; for 1–12 days the patient may hover between complete recovery and disastrous paralysis. Within a few hours the fate of tens of thousands of motor nerve cells may be decided by some stimulus to rapid multiplication of the virus. The factors which influence the vulnerability of nerve cells include: (1) physical activity between the minor illness (general symptoms) and the major illness (meningeal and paralytic symptoms), and especially after onset of the meningeal stage[3,6]; (2) local trauma, tonsillectomy, and parenteral injections; (3) transport in the acute stage over long distances[7,8]; (4) possibly pregnancy and menstruation[9]; and (5) upper respiratory infections.[10] Once the process of destruction has started it is quickly completed, and in cases of severe paralysis 60–90% of the motor neurones may disappear within a few days. All the other anterior horn cells, though showing chromatolysis in the acute stage of the disease, appear normal within 4–5 weeks, and wallerian degeneration does not occur in their axons.[11] Thus it is useless to base treatment on a policy of waiting for regeneration of nerves. Recovery of function over, say, 18 months, is due simply to hypertrophy of non-paralysed muscle and enlargement of the surviving neurone cells and fibres.[12]

In the care of muscles and joints no rigid splinting, plaster casts, or orthopædic frames should be applied even in the acute stage when paralysis is developing. Pain should be relieved with analgesics, and gentle passive movements of the joints through their full range should be practised from the first day. In some cases with asymmetrical paralysis muscle spasm or "protective fixation" in the acute stage may lead to contracture deformity if left untreated. Passive movements and maintenance of a neutral position by simple means, such as sandbags, footboards, and pillows, are the best remedies. Spasm should have disappeared about a month from onset. Some form of heat may be helpful for pain and muscle spasm, but hot packs are unnecessary: "There is no reason to suppose that the life of a single nerve cell has ever been saved by the use of hot packs." Muscle shortening is best countered by gentle passive movements and frequent changes of position. The main benefit from the Kenny treatment has been to counter the suggestion that paralysed or paretic limbs should be rigidly splinted. Physiotherapists must learn to start active movements after the first two weeks of the disease, and to introduce without delay active vigorous exercises to the point of fatigue. This will give maximal muscle recovery in a matter of weeks rather than months or years.[13] RITCHIE RUSSELL has failed to confirm that deliberately induced fatigue harms paretic muscles in the recovery stage. On the contrary, it gradually induces hypertrophy and greatly speeds reablement. After 2½ months the patient should be spending most of the day exercising the weak muscles and not the strong, so as to attain the best possible function with the least deformity. Limbs and trunk may be supported against gravity by suspension with slings and springs, in a water bath, or by other means. Trick movements which offend the

"well-trained" physiotherapist should not be discouraged. **Ritchie Russell** holds that the patient should find his own way of executing movements so long as a watchful eye is kept on any developing deformity. Deformity may be countered by alternate active movement and rest in the prone position for an hour or two, three times a day. Even the severely paralysed should be walking or in a wheeled chair and ready to go home 5–8 months from onset. Long periods of hospital treatment are psychologically and physically undesirable, and plans for the future should be discussed as soon as the likely permanent disability can be assessed.

Ritchie Russell remarks that mobile teams are needed to deal with sharp outbreaks in small communities. Denmark's experience last year, however, when there was a very severe outbreak with much respiratory paralysis which soon exhausted the usual mechanical resources, suggests that such teams should be organised on a European rather than a national level, and possibly the European Office of W.H.O. might give thought to this. Denmark's adversity, however, has yielded valuable lessons, for, as Professor **Lassen**[14] reported last week, the death-rate from respiratory insufficiency was reduced by half when early tracheotomy with insertion of a tightly fitting rubber cuff tube was combined with bag ventilation, repeated aspiration and bronchoscopy, postural drainage, and the use of a stomach-tube.

Marasmus Today

Medical progress has made such terms as "marasmus," "athrepsia," and "congenital debility" almost obsolete, but the names remind us of the diagnostic difficulties of our predecessors, who, lacking the tools of modern medicine and the means of biochemical analysis, were denied the opportunities for accurate differential diagnosis which modern pædiatricians enjoy. The term "marasmus" was applied to a great many serious disorders which could not be differentiated, and in which gross emaciation was common. It is now clear that the bulk of these children were suffering from malnutrition due to underfeeding, from pyloric stenosis, nervous regurgitation, or pancreatic fibrosis, or from infections, such as gastro-enteritis, in which no known pathogens could be isolated, or from metabolic disorders such as idiopathic renal acidosis, hypervitaminosis D, cystinuria, and hypertrophy of the adrenal cortex. In the past most children who failed to thrive in infancy were vaguely said to have some digestive disorder, and many elaborate feeding formulæ were advised, usually without benefit, but we now know that many of these infants were either grossly underfed or suffering from a low-grade gastro-enteritis caused by coliform organisms, notably certain types of *Bacterium coli*, which tend to be pathogenic in infancy.[15] The era of strict theoretical feeding of infants has passed and the pendulum has swung back to the physiological custom of feeding to repletion, for infants know when they have had enough, and there is little danger of overfeeding. Often, atypical *Bact. coli* are not sought in routine bacteriological examinations, so a search should be specifically requested in infants who are suspected of having gastro-enteritis. Fortunately, certain of the newer antibiotics, particularly chloramphenicol, are often capable of curing the infection and restoring health and a rapid gain in weight. It is important to bear in mind that although these children often pass more stools than usual, the stools may look normal. A more general appreciation that underfeeding and coliform gastro-enteritis are common causes of failure to thrive (and even of marasmus) in infancy, has, more than anything else, put a stop to unnecessarily elaborate feeding methods, and it has led to the routine use of simple formulæ such as fresh boiled milk, water, and sugar, or National Dried Milk, water, and sugar. Indeed, there are relatively few conditions in which the infant fails to thrive where special modification of the diet is necessary—pancreatic fibrosis is one.

Idiopathic renal acidosis of infants, first described by **Lightwood**[16] in 1935 as "nephrocalcinosis infantum," is one of the most interesting causes of failure to thrive in infancy. The term "renal acidosis" was introduced in 1939 by **Hartmann**,[17] who was the first to attribute this disease to renal dysfunction. This curious biochemical disorder has been closely studied in the last few years, and the increasing number of cases now being identified shows that it is by no means uncommon. **Doxiadis**[18] has lately discussed the subject, and contributed 9 cases of his own. The infants were usually normal for the first one to six months of life, after which anorexia, vomiting, and constipation began. Progressive listlessness and an ashen-grey colour developed, and they no longer gained weight satisfactorily. The disease fluctuated sharply with periods of clinical improvement and deterioration. Urinary tract infection was a common feature. The main diagnostic finding was the pronounced discrepancy between the persistent acidosis in the blood and the alkalinity of the urine. Occasionally the urine was slightly acid, but the pH was never below 6.0. Indeed, the inability of the kidney to form a sufficiently acid urine, and so to maintain the normal blood pH and prevent acidosis, is the fundamental fault in this disease. **Latner** and **Burnard**[19] demonstrated that the essential defect is a lowering of the renal threshold for bicarbonate, caused by the inability of the proximal tubules to reabsorb it. **Doxiadis** believes that nephrocalcinosis, which has been regarded by some as synonymous with idiopathic renal acidosis of infancy, is not one of the main features of the disease, but tends to develop when renal acidosis is allowed to continue untreated for many months. The manifestations of a distal tubular lesion—thirst, polyuria, and urine of low specific gravity—which are the result of nephrocalcinosis, did not develop in **Doxiadis**'s patients who were adequately treated. They were given large amounts of alkali to counteract the acidosis: the dose was usually 5–10 g. of sodium and potassium citrate daily, with a sodium/potassium ratio of 2 to 1, until the infants had been well and gained weight for two to four months. Fortunately, the defect in the proximal renal tubule, the cause of which is unknown, is self-limiting, and if urinary or intercurrent infection or permanent damage from nephrocalcinosis and the patient is satisfied. But the experienced senior sister is apt to receive such invitations with reserve; for she knows there are occasions when even the simplest technique goes wrong and the patient demands redress. Who is then to take the blame, the nurse or the doctor? Moreover, such disasters are not necessarily trivial: in a case reported in the press [1] last November a patient lost her life.

> A doctor left a nurse in charge of a patient who was receiving a blood-transfusion. He told the nurse to take the blood-pressure at a given time, and if the systolic pressure was below 90 mm. Hg to connect and give another bottle of blood. The nurse took the blood-pressure at the time appointed, got a reading of less than 80 mm. Hg, noted this on the chart, and sent for another bottle of group-O blood. The bottle had to be obtained from a refrigerator in a neighbouring hospital, and, owing to some mistake in the transmission of messages, blood of group A was supplied. Transfusion with this blood was begun, and after the patient had received 3 oz. or less she died. At the inquest a doctor giving evidence said that responsibility for making sure that blood of the correct group is transfused rests on the person who attaches the bottle to the apparatus.

Most of us will agree that it is not part of a nurse's functions to take the blood-pressure, or to act on such a blood-pressure reading, or to give a blood-transfusion. This particular nurse seems to have obeyed instructions exactly; and the fact that she gave the wrong blood was no fault of hers. It was not her duty to check the accuracy of the label on the bottle sent from the dispensary. Nevertheless the mistake was made, and in the anxiety to apportion blame correctly it was naturally asked whether the extra bottle of blood had perhaps been given unnecessarily. The nurse was thus subjected to examination and criticism to which she should never have been exposed.

The Royal College of Nursing are rightly concerned about the whole question of delegation of the doctor's duties to the nurse; for if she accepts such assignments she lays herself open to claims on the ground of professional negligence (even though the thing done is outside her proper field). In a memorandum [2] circulated to the regional hospital boards and boards of governors of teaching hospitals the council of the college affirm that the syllabus of the General Nursing Council must be regarded as indicating the normal range of the State-registered nurse's duties; and though any nurse must expect, in emergency, to undertake duties outside this range, she should not undertake the day-to-day practice of procedures normally belonging to the doctor. Estimation of blood-pressure, withdrawal of blood from veins, and intravenous injection all fall outside the syllabus. The council propose that, unless gross negligence on the nurse's part is proved, the hospital authorities should definitely assume responsibility for any act she may undertake beyond the nursing duties. The council also make a second important point—that a nurse who is attending to her own work has no time to deputise for the doctor. A doctor who uses his nurses freely for such purposes is depriving the patients of nursing care to a greater extent than perhaps he recognises. Senior nurses say that if a trained nurse in hospital accepts the full implications of nursing, and does not have to spend her time in extraneous duties—either filling in domestic gaps at one end of the scale, or concentrating on quasimedical techniques at the other—she should have more than enough to do in caring for her patients, teaching, supervising students, and administering her ward. Undue responsibility is placed on the nurse, again, the council point out, when she is asked to get the patient's signature to the new "consent to operation" form now in use in many hospitals. This states that the patient has received an explanation of the nature of the operation he is to undergo, and the effect to be hoped from it. Though it is certainly a doctor's task to give him this explanation, it is sometimes delegated to a nurse, who is not always in the surgeon's confidence about what he intends to do, and in any case has not had the appropriate training for giving such an explanation. We agree with the council that every patient should be told plainly, by a doctor, to what he is agreeing.

There is every reason to treat nurses as colleagues: that is the proper relationship for professional people engaged in a joint enterprise. But we must not forget that nursing and medicine are two different disciplines, both requiring long training, and that proficiency in one does not ensure proficiency in the other, as a doctor's bandaging too often reveals. We should see quite clearly what we are doing when we delegate one of our own tasks to a nurse: we are putting her in a false and dangerous position which may result in damage to her professional reputation, and we may be hindering her in her duty to her patients.

The Coronation Honours

THE three new knighthoods for members of the medical profession in this country are conferred on the president of the General Medical Council, the president of the Royal Society of Medicine, and the director-general of the medical services of the Royal Air Force. Prof. David Campbell, in his sometimes forbidding office, has shown a wisdom and humanity that have strengthened the respect and affection in which he is held; Dr. F. M. R. Walshe, with his intellect and spirit, has long been the most valuably unrepresentative of our representatives; while Air Marshal Kilpatrick is a man whom all his associates, inside his service and outside it, will be glad to see honoured. The K.C.M.G. bestowed on Sir Bennett Hance is given for the important work he has done for the Commonwealth since he ceased to have charge of the Indian Medical Service. Among the administrators of the National Health Service, knighthoods are conferred on Mr. Frederick Messer, chairman of the Central Health Services Council, and on Mr. J. W. Bowen, chairman of the North-East Metropolitan Regional Hospital Board, while the Hon. A. J. P. Howard, chairman of St. Thomas's Hospital, is created K.B.E., and Miss E. M. R. Russell-Smith, an under-secretary of the Ministry of Health, D.B.E. Mr. J. E. Pater, the under-secretary especially concerned with hospitals, is appointed C.B., and Mr. W. G. Senior, principal dental officer of the Ministry, is promoted C.B.E. Mr. H. N. Linstead, M.P., secretary of the Pharmaceutical Society, receives a knighthood, and Miss D. M. Smith, matron of Guy's and chairman of the General Nursing Council, becomes C.B.E. The medical list which we print on p. 1149 takes account of distinguished work of many different kinds done in many different parts of the Commonwealth. The recognition given will be welcomed most by the colleagues who know how well it has been earned.

TABLE II—PRINCIPAL CAUSES OF DEATHS IN CEYLON AND WESTERN COUNTRIES

Causes	Per 1000 deaths				
	Ceylon		Eire	U S A	England and Wales
	1945	1948	1947	1947	1947
Bowel infection and infestations	118	114	19	6	12
Tuberculosis in all forms	26	43	66	34	49
Malaria and pyrexia	167	82	—	—	—
Cancer and other tumours	6	10	90	132	155
Diseases of the heart circulation and intracranial vascular lesions	57	72	366	688	474
Pneumonia and bronchopneumonia	85	86	42	38	64
Maternal deaths	58	25	3	4	2
Infantile deaths	128	154	57	46	30

these two trends will determine whether the Ceylon death-rate will remain stable at the new low level (table II)

Comparison with Eire

Cardiovascular Diseases

In Western countries diseases of the cardiovascular system (with the accompanying or attendant dangers of vascular intracranial lesions and possibly nephritis) account for 1 in 3 or 1 in 2 of all deaths (Ceylon 1 in 14) As they are diseases of the middle and later years of life they may be more prevalent in Western countries because people live longer there Age-specific deaths from diseases of the circulatory system are not available in Ceylon, but even supposing that all such deaths in Ceylon occur from 55 years and upwards, the death-rates per 1000 in Ceylon are less than those in Eire (Ceylon males 6 9, females 5 5 in 1949, Eire, males 31 4, females 31 7 in 1947)

Cancer

Similarly cancer, another hazard of the later years of life which accounts for 9–15% of all deaths in Western countries, produces less than 1% of deaths in Ceylon The age-specific mortality-rates show that for all age-groups the rates are lower in Ceylon than in Eire (table III) Part of this difference may be due to inaccurate diagnosis, although even among the better-educated classes in Colombo, where good medical facilities are available, the incidence of cancer is still low by Western standards

The death-rate from cancer has not varied significantly over the past twelve years, although the number of deaths recorded has been rising steadily The most common sites for cancer in Ceylon are the buccal cavity (42% of deaths from cancer in males and 23% in females), the digestive tract (25% in males), the uterus (23% in females) In Eire cancer of the digestive tract (especially cancer of the stomach and rectum) is the main cause of death from malignant disease Thus the distribution of cancer does not seem to be the same in Ceylon and Eire But it may be more accurate to say that, since cancer of the buccal cavity is an easily recognisable condition, more deaths in Ceylon are registered as due to this cause than to any other malignant growth

TABLE III—DEATH-RATES PER 100,000 OF THE POPULATION IN CEYLON AND EIRE

Causes of death	Death-rate in Ceylon (1948)	Death-rate in Eire (1947)
Diseases of heart	39 1	374 1
Other diseases of circulatory system	7 7	30 1
Vascular intracranial lesions	29 5	101 7
Cancer and other tumours	13 0	133 3
Diseases peculiar to first year of life	203 1	84 4
Puerperal eclampsia	25 9	—
Puerperal septicæmia	15 2	1 1
Tuberculosis of respiratory system	53 2	95 3
Other forms of tuberculosis	4 2	29 2
Bronchitis—all types	16 6	44 3
Pneumonia—all types	114 3	62 8
Other respiratory diseases	27 0	20 9
Diarrhœa and enteritis	71 1	28 5
Peptic ulcer	0 6	8 6
Appendicitis	0 7	3 1

Infant and Maternity Mortality

In Ceylon, the dangers to life during the first post-natal year are 3 to 4 times greater than in Eire The causes of infant deaths in Ceylon differ from those of Western countries Most of the reported causes in Ceylon are vague and unsatisfactory Thus "convulsions," "congenital debility," "prematurity," and "rata" each account for about a fifth of the registered infantile deaths How accurately the differential diagnosis between congenital debility, prematurity, and rata can be made is difficult to say Together they probably reflect the poor nutrition of the population, and for this reason the differences between the causes of infantile deaths in Ceylon and in the British Isles are noteworthy Diarrhœa and enteritis are 3 to 4 times more common as a cause of these deaths in Britain than in Ceylon, respiratory diseases are at least twice as common, and injury at birth more than ten times as common Since 1946 the infant-mortality pattern has tended to become Westernised The proportion of deaths occurring during the first month of life has increased, because, although the mortality-rates at all age-periods have been reduced, the reduction has been proportionately greater in the 1–12 months period.

The maternal-mortality rates are also higher than in Western countries, and this is true for most of the principal causes of maternal mortality

In Eire, as in Ceylon, hæmorrhage causes more deaths during the puerperium than during pregnancy, while toxæmia is a commoner cause of death, in both countries, during pregnancy than it is during the puerperium Puerperal sepsis is a commoner cause of death in Ceylon than other infections, the reverse is true in Eire Puerperal convulsions are not given as a cause of death in Eire, but are the major registered cause of death in Ceylon

Tuberculosis

The morbidity and mortality rates from tuberculosis in Ceylon have remained fairly stable since 1941. The recorded mortality-rates compare favourably with those of European countries, but this may be due to the difference in the accuracy of diagnosis Lack of social responsibility about tuberculosis is linked with inadequate diagnostic and therapeutic services so that a true picture of the distribution of the disease in Ceylon cannot be given

The available figures show that tuberculosis of the respiratory system accounts for 93–94% of all deaths from tuberculosis, and the number of recorded deaths from this cause seems to be slowly increasing The recorded death-rate from tuberculosis in Ceylon is lower at all ages than the rate in Eire In England a far smaller proportion of deaths are recorded as due to tuberculosis in other parts of the body than the respiratory system

Respiratory Diseases

With the drop in the mortality from malaria since 1946, diseases of the respiratory system have become one of the major causes of death in Ceylon, being responsible for about 1 in 10 of all deaths Bronchitis is a commoner cause of death in Western countries, while pneumonia is a commoner cause in Ceylon

Digestive Diseases

Diseases of the digestive system account for about 1 in 14 deaths in Ceylon Since 1946 the total deaths and the death-rates from these diseases have fallen owing to the decrease in deaths from diarrhœa and enteritis These diseases account for 70–80% of all deaths from diseases of the digestive system in Ceylon In Eire the proportion of deaths from diarrhœa and enteritis is lower, and the proportion of deaths due to peptic ulceration, appendicitis, hernia, intestinal obstruction, and diseases of the gall-bladder, bile-ducts, and pancreas is correspondingly greater

In most countries male infants have a higher mortality than female infants, and in Ceylon, during 1937–45, 1144 male infants died to every 1000 deaths of female infants

Annotations

PUBLICITY

CLOSE readers of the newspapers will have observed a recent change of practice as regards reports on charges of unprofessional conduct against doctors. Before the Medical Act, 1950, came into force, such charges were heard by the General Medical Council as a whole, and the council instructed the press that they should not publish reports before a decision was reached. Under the new procedure the hearing is undertaken by the Medical Disciplinary Committee of the Council; evidence may be (and in practice is) taken on oath; and newspapers are at liberty to report the proceedings hour by hour, as they do in cases heard in ordinary law-courts. Though the first applications for restoration to the Medical Register were heard by the Medical Disciplinary Committee in camera, all subsequent applications have been heard in public. One curious result of the changes under the new Medical Act is that evidence which could not be reported when it was given in the divorce courts becomes reportable when repeated during the hearing of cases by the committee.

One of the cases heard at the last session[1] attracted much attention in the press. On the Wednesday evening it had been the subject of an application for an adjournment, but the newspaper reporters generally decided that no reference to it could be made at that stage because the charge had not yet been read. One reporter, however, observed that the committee's notice forbade mention of anything in the programme of business "unless and until the case has come before the committee"; and his newspaper took the view that, as an application for adjournment had been made, the case could now be said to have come before the committee. This newspaper had already secured some photographs, and on Thursday morning it was able to offer its readers what it regarded as a scoop. We may add that the likelihood of widespread publicity will increase rather than diminish; for cases heard by the Medical Disciplinary Committee are in future to be reported by the news agencies (though the reports will not necessarily be circulated) and will more easily find their way into the local press.

The attitude of the newspapers towards professional bodies, and of professional bodies towards the newspapers, provides some curious contrasts. The disciplinary proceedings of the General Nursing Council, for example, though open to the public, are rarely if ever reported: even the nursing press does not give details of cases, and nurses consequently do not know the circumstances in which their disciplinary body takes action. For our own part we regard it as an obligation to report medical disciplinary proceedings—usually as briefly as possible, but more fully where any question of principle seems to be at stake. Objectionable though publicity may be, it is one of the safeguards of justice, and we should be sorry to see our profession adopt the privacy of the Inns of Court or the Law Society, which announce only their decisions, and thus leave the public without means of knowing what the respondent found to say in his defence.

MERCURIALENTIS

THE accessibility of the transparent structures of the eye to biomicroscopy with the slit-lamp and the binocular microscope has enabled these tissues to be displayed and examined under conditions of critical illumination and with a magnification sufficient to show, for example, the minute structure of the crystalline lens and the cornea. Most lesions of these structures are of purely ophthalmological significance: but in an increasing number of cases ocular signs are providing accurate evidence of general metabolic disturbances or intoxications—for example, the Kayser-Fleischer ring of hepatolenticular degeneration, the characteristic opacities of endocrine cataract, and the corneal and lenticular changes of the various types of metallic poisoning. In this last group, Hunter and Lister[1] emphasise the value of ocular signs in the early detection of chronic mercury poisoning, in which there is a characteristic brownish discoloration of the anterior lens capsule—mercurialentis. This change appears some considerable time before the onset of visual deterioration or general signs of mercury poisoning. It has been seen in people who have been exposed to mercury for long periods, usually in some industrial process involving contact with the metal or its salts. Hatters, who employ solutions of mercury salts in felting processes, may have mercurialentis as the earliest sign of absorption of mercury[2]; and thermometer makers may be similarly affected, either by the inhalation of vaporised mercury[3] or by accidental impregnation.[1] The slit-lamp microscope signs of mercurialentis have also been seen in those who make or repair mercury switches.[4] Chronic poisoning from mercurial compounds used medicinally is nowadays rare; but long-continued use of the yellow oxide, readily accessible as the ubiquitous "golden eye ointment," can lead to permanent discoloration of the eyelids and conjunctiva, and mercurialentis from this cause has been described by Fisher[5] and by Abramowicz.[6]

Mercurialentis is clearly of importance to industrial medical officers who are on the lookout for mercury poisoning. Locket and Nazroo,[4] who found no relation between the general clinical evidence of mercury intoxication and the appearance of the ocular signs, made the helpful suggestion that these signs might be used to detect the early results of long-continued exposure to low concentrations of atmospheric mercury. As far as the eye ointment of mercuric oxide is concerned, there are now so many equally effective treatments available that it is doubtful whether we can justify its continued use, with the possibility of discoloration of the superficial ocular tissues and lens changes.

PROPHYLAXIS IN MEASLES CONTACTS

IT is now generally agreed that human gamma-globulin is a safe and adequate means of attenuating, or even preventing, measles in contacts, provided that it is given not later than the sixth to ninth day of the presumed incubation period, assuming the incubation period to begin on the date of contact. The difficulty generally lies in deciding to what extent it should be used. It has been said that 1 pint of blood is needed to produce 1 gramme of gamma-globulin, and during a measles epidemic the number of contacts is so enormous that routine administration is impossible. It is generally restricted, therefore, to young children who are already suffering from an acute disease, such as whooping-cough or pneumonia, who are debilitated in some way, or who are inpatients in children's wards where the infection must be controlled if the work of the hospital is to continue.

An entirely different situation arose in the 1951 Greenland epidemic[7] in virgin soil when 99·8% of the population were affected. It was found possible to give one rather small dose of gamma-globulin to 520 people immediately after the first case of measles appeared in a certain district. This protection was given to children under 2 and people over 60, to pregnant women, and

In most countries in the West this higher male death-rate persists through life, but in Ceylon females have a consistently greater death-rate after the first year of life The reduction in the death-rate since 1946 has been proportionately similar for males and for females in all age-groups The absolute reductions for females have been greater than those for males, and, if this continues, the proportion of females to males in the population may be increased in the future At all ages and for both sexes, however, the mortality-rates for Ceylon are higher than for Britain so that, even with present medical knowledge and techniques, there is still hope for improvement in Ceylon

An American Comparison

Though Ceylon and Eire have similar crude total death-rates, the relative importance of the different causes of death varies greatly Presumably the mortality experience reflects the morbidity experience It is difficult to obtain reliable information on morbidity, but some comparisons are possible, since similar surveys of disabling illness have been made in Ceylon in 1950 and in the United States in 1949 (U S Public Health Service 1950)

In each survey the same concept of disability was used—viz, if a person was unable to do his regular work because of illness, he was said to be disabled Such a definition could be objectively applied to only the working population, and the surveys of disabling illness related only to the 14–64 age-group Only people unable to work on the day of the investigation were considered, and the unemployed were not included unless they were too ill to have worked Regular work was taken to include household duties by the women of the family and could be full-time or part-time

Neither survey sampled the inmates of such institutions as prisons, mental hospitals, and orphanages, nor the military population, nor transients with no fixed abode Each study was based on door-to-door interviews—17,946 households (1 in 80 of the total population) in Ceylon, and 25,000 households in the U S A

PREVALENCE OF "DISABILITY"

The Ceylon survey showed that, on an average week-day, the percentage of people aged 15–64 years in the civilian non-institutional population who were unable to work because of illness was 5 32 ± 0 096 (U S A 4 72) The average number of days of disability which might be expected in a year for each person in the sample group was 19 4 days (U S A 17 2 days)

These rates and durations are not strictly comparable since the two sample populations had different age and sex proportions The American sample, being composed of more middle aged people, would be more likely to suffer from the chronic, disabling illnesses of middle and later life A more accurate comparison can be made by applying the age specific disability-rates found for Ceylon to the American population Such a calculation indicates that, if the population of Ceylon had the same age-composition as that of America, then the disability rate in Ceylon would be 5 90% Similarly the average number of days of disability that might be expected in a year for each person would be 21 5 days (17 2 days in America)

In the Ceylon sample the prevalence of disabling illness increased with advancing age until, from 55 years onwards, 1 in about every 9 persons was disabled (In the U S A people aged 25–34 years had a lower prevalence of disabling illness than people in the other working age groups) The prevalence of disabling illness among men was lower than among women in the age group 15–54 years, the female prevalence in the U S A was only higher in the age-group 20–44 years These differences are comparable with the different sex mortality ratios in the two countries Of the disabled, over 34% in Ceylon had been disabled for three months or longer (in the U,S A 53%)

The types of diseases which caused disability in the Ceylon inquiry are set out in table IV

TABLE IV—PREVALENCE OF DISABLING ILLNESSES EXPRESSED AS A PERCENTAGE OF ALL CAUSES

Illness	Males %	Females %	Total %
Infective and parasitic diseases	32 7	30 2	31 1
Diseases of the blood	6 6	2 5	4 6
Diseases of the nervous system	10 0	7 6	8 8
Diseases of the circulatory system	1 8	0 9	1 3
Diseases of the respiratory system	6 5	8 0	7 3
Diseases of the digestive system	5 8	6 1	5 9
Diseases of the genito urinary system	1 2	1 9	1 6
Pregnancy childbirth, and puerperium	—	10 3	5 2
Cancer and tumours	0 4	0 3	0 3
Rheumatic diseases	13 8	14 4	14 1
Diseases of the skin	7 7	4 7	6 2
Diseases of the bones and joints	0 4	0 1	0 2
Diseases of the eye	2 1	0 9	1 5
Accidents	6 4	1 9	4 1

Physiological Characteristics

The morbidity and mortality patterns in Ceylon differ from those of the United Kingdom or U S A The differences are associated with, though not necessarily related to, differences in diet (Cullumbine 1951), in physique (Cullumbine 1949b), and in many physiological measurements The latter is not surprising, for some physiological characteristics have been related to the physical proportions of the body—e g, the surface area of the body has been correlated with the rate of basal metabolism, the blood volume, the vital capacity, &c If the body surface area varies, these physiological factors may well vary too

TABLE V—BODY COMPOSITION OF 50 CEYLONESE MALE STUDENTS AGED 21–25

Component	Mean	% of total body weight	% composition for British subjects (McCance and Widdowson 1951)
Weight (kg)	49 8	—	—
Height (m)	159 2	—	—

Fat (kg)	2 59	5 2	7 2–22 4
Cell mass (kg)	33 58	67 4	54 2–62 0

In fact the smaller, more ectomorphic, Ceylonese have lower resting systolic and diastolic blood pressures (Cullumbine 1949a), faster resting pulse rates, lower basal-metabolic rates (Cullumbine 1950), lower vital capacities, lower maximum breathing capacities, smaller residual air volumes (Cullumbine 1949c) than occidental peoples The Ceylonese values are typical of a person with a linear body build—i e, the ectomorph Some of their other physiological characteristics are also those of the thin man For example, their body composition—plasma volume (given by T 1824 dye), extracellular fluid (thiocyanate), fat content, cellular mass (determined by the method of McCance and Widdowson 1951)—is similar to that of the active thin man in the Western hemisphere (table V)

The absolute values of the mean extracellular fluid volume and the plasma volume are lower than those for average British or American subjects—3 13 litres plasma volume, 17 13 litres extracellular fluid volume (Henschel et al 1947)—but they form higher proportions of the body weight Similarly their fat content is low and their cellular mass relatively high The fat content of the body is low in undernourished or starved people (McCance and Widdowson 1951), who also have low blood pressures (Brozek et al 1948) an increased proportion of extracellular fluid (Henschel et al 1947), to tuberculous patients. In many of these cases the prophylactic could not exert its full effect, because measles was not always contracted at the first exposure but later when the effect of the gamma-globulin had partially or completely worn off. Yet even under these difficult conditions the measure was amply justified. There was obvious attenuation in many of the inoculated patients, even in adults, and there was no such attenuation in those who had not been inoculated. In an attenuated attack the prodromal stage was shortened, the rash was much less profuse, and there were fewer days of fever. Complications in those under 55 who were inoculated were less common than in the controls. The death-rate was also lower among those inoculated, when the deaths of tuberculous patients and premature infants were discounted. It was concluded that limitation of the spread of measles under such conditions by specific prophylaxis was impracticable, but that it was well worth trying to protect children under the age of 2, pregnant women, and old people. And in tuberculosis, gamma-globulin should be given first to those who have a real chance of recovery, and the dosage in such adults should be 2 to 3 g., which is 8–12 times the amount usually given to children under 2. Where exposure to infection persists, this dose should be repeated after an interval of two to three weeks.

PRESERVATION OF THE FAMILY

"THE family is tough, resilient, and adaptable," said the Bishop of Sheffield on May 20. "Human folly cannot destroy it, but it can hurt, corrupt, and weaken it." He was inviting the House of Lords to consider the effects of recent legislation and other influences on the well-being of the family; and it soon appeared from the debate that the Lords are as likely as the rest of us to form constellations of ideas, beliefs, and prejudices, and what one person sees as an evil for the family another may see as a good. Nevertheless there are some fixed stars in this zodiac which all can steer by; and one of these is that family well-being cannot exist apart from the family. Any measures which help to keep the family together, then, are worth pursuing; and the speakers had this well in mind. The Bishop of Sheffield suggested that nowadays, when the country is impoverished, and families are too small to keep mothers fully occupied, those with children over three years of age should be free to go to work, if they wish; it would therefore be an ill-chosen economy, he thought, to close nursery schools and classes or reduce the number of school-dinners. But though a good nursery school or class, open for a few hours in the morning and afternoon, benefits the child and refreshes the mother, it does not free her for full-time work in industry. Only a day-nursery can do this, and then only at the cost of keeping the child from his mother from early morning until, tired by a factory working-day, she fetches him at night. The three-year-old, or even the four- or five-year-old, is none the better for this kind of deprivation, and we believe that there is a strong case for not encouraging mothers of young children to do more than part-time work in industry. The Marquess of Salisbury would prefer to see them doing none at all, for, as he said, the basis of education, and especially of religious education, used to be the teaching given by mothers to their children in the homes; and no school syllabus, however admirable, can take the place of it. Since family life can only be conducted in a family home, he was anxious to see more houses built.

On a long view, it is in the interests of the family, the Bishop of Sheffield argued, that the principle of equal pay for equal work should go with family allowances. He noted, as many have done,[1] the temptation to solve the problem-family problem by dissolving the family—often by putting the children into an expensive institution, and the mother or father into an expensive prison. Our best resource for problem families has so far proved to be the family service unit, and he asked whether enough thought is being given to training people for this sort of work. Families often disrupt themselves, however, without any interference from a benignly intending State; and indeed, the growing divorce lists indicate that there are many more broken homes in England today than in the past. Lord Pakenham urged the need for the best marriage guidance or other advice we can give to help husbands and wives to make a greater success of their marriages—a need underlined by the Earl of Selkirk, who said that free legal aid is available to dissolve marriage but only very modest help is given to the bodies which work to maintain the married state.

Lord Beveridge, thinking of the physical health of the family, discussed the cost of social insurance, and said there were strong arguments for getting more of the money needed by taxation, and a great need to stabilise prices. In so far as we are treating people inadequately under National Insurance, he said, we are treating most inadequately those with large families.

The impulse to hold together, the binding centripetal force, is inherent in the family; for after all, in spite of disruptive forces, most families still keep their integrity. Large families, perhaps, generate more of this force: at all events, they do not seem to have flown apart as readily as modern small families. Perhaps, too, it takes more rugged selfishness to desert a large number of children than to desert one or two. But the damage done to the individual child by breaking up the family does not vary with family size; and an understanding of this fact should help parents to recover that principle of dedication to a common purpose which our times have undermined.

PLACENTAL BLOOD-FLOW

THE fœtus depends for its livelihood entirely on the exchanges in the placenta. The rate of maternal blood-flow in that organ is, therefore, of fundamental importance. Until now only indirect information has been available for the human species; and Browne and Veall[1] are to be congratulated on the technique they have evolved for direct studies. The first step is to localise the placenta; and this is done by injecting intravenously a small amount of radioactive sodium.[2] Only cases in which the placenta is on the anterior uterine wall are suitable for the blood-flow studies. Three days are allowed to elapse in order to reduce residual radioactivity to a negligible amount. The technique depends on the injection into the choriodecidual space of 10 μC of radioactive sodium in about 1 ml. of saline, and the subsequent recording of counts over the injection site. The disappearance-rate of the Na^{24} can thus be plotted, and the resultant curves in successful cases are of exponential form. The technical difficulty lies in finding the choriodecidual space. When the needle point is in the space blood flows freely into the syringe; and with experience Browne and Veall found that they could appreciate the various layers through which the needle point was passing. The nature of the curve of the disappearance-rate also confirms that the correct layer has been reached. In eight normal cases studied between the 38th and 40th weeks, the mean half-period was 21 seconds with a range of 13–30 seconds. In seven patients at the same gestation period, but with pregnancies complicated by pre-eclampsia or hypertension, the mean half-period was 65 seconds with a range of 47–102. There was no significant difference in results between the patients with pre-eclampsia and those with chronic hypertension. Browne and Veall admit that and a change of somatotype to that of ectomorph (Lasker 1947)

Our Ceylonese subjects came from well to-do families, so presumably they were eating sufficient food. Moreover they differed from undernourished people who show an increase in the actual volume of extracellular fluid and also a reduction in cell-mass The body composition of the Ceylonese probably represents an adaptation to their environment They need only a minimal body-fat content, and their small body-weight is partially due to this Chapman et al (1950) have found that on rice fruit diet American subjects reduce their body fat total body-weight, thiocyanate space, and blood-pressure

One importance of the physiological characteristics and the anthropometric characters of the Ceylonese people lies in their relation to dynamic fitness (Cullumbine 1949d) Thus the resting pulse-rate is correlated negatively with the ability to perform moderate effort, and the Ceylonese, who have a relatively fast pulse-rate, will be handicapped in this respect compared with Western people The resting systolic blood pressure is correlated positively with the ability to run with speed with strength, and with the ability to sustain moderate muscular effort to exhaustion All these aspects of dynamic fitness will probably, therefore, be better performed by Western races than by the Ceylonese, who have a relatively lower resting systolic blood-pressure Similarly speed, strength, and the performing of moderate exercise to exhaustion demand a stocky physique and are positively correlated with body-weight, so that the slimmer and lighter Ceylonese will be further handicapped compared with Western people On the other hand the performance of rapid and severe effort to exhaustion is best done by subjects with a slim physique, a body type more characteristic of the Ceylonese than the British Conversely, the ability to perform rapid and severe effort to exhaustion is positively correlated with the vital capacity, and the Ceylonese have a relatively small vital capacity

The people of Ceylon, therefore, have, on an average, different physical and physiological proportions, different functional potentials, and different morbidity and mortality experiences from the people of Britain To what extent these differences are related to the varying environments—climatic, social, economic bacteriological, parasitological—is still doubtful

Occasional Survey

CHRONIC BULLOUS DISEASES

THE diagnosis of chronic bullous eruptions has always been difficult and sometimes impossible The more cynical have said "Wait and see If the patient dies, it is pemphigus, if not, it is dermatitis herpetiformis or erythema multiforme" Recent histopathological work by Civatte and others, cytological studies by Tzanck, and fresh knowledge of the biochemistry of blister fluids, have all helped to clarify the problem and to give the physician more confidence in deciding on the prognosis In addition, corticotrophin (A C T H) and cortisone have proved effective weapons in the control of these previously uncontrollable conditions

Lever,[1] who has reviewed present knowledge of pemphigus, believes that there are two sorts of malignant pemphigus, each with its own variants Thus pemphigus vulgaris has as a variant pemphigus vegetans in which there is more tissue response than in pemphigus vulgaris Pemphigus vegetans itself may be malign (Neumann type) or relatively benign (Hallopeau type, *pyodermite vegetante*), though this may terminate in the malignant form The other sort of malign pemphigus is pemphigus foliaceus, with a relatively benign variant, pemphigus erythematodes (Senear-Usher syndrome)

The clinical differentiation of all these types of pemphigus from the straightforward case of dermatitis herpetiformis or erythema multiforme is easy, but there are other relatively benign bullous dermatoses that may easily be confused with pemphigus There is, first, bullous pemphigoid, called by some bullous or senile dermatitis herpetiformis, and secondly there is benign mucous-membrane pemphigoid, also known as conjunctival or ocular pemphigus All these maladies can be differentiated today with some confidence by clinical observation combined with histopathological, cytological, and biochemical techniques

PEMPHIGUS VULGARIS

In pemphigus vulgaris the flaccid bullæ usually arise on normal-looking skin, rupture easily, and tend spontaneously to increase in size The denuded areas left by ruptured bullæ extend peripherally and show a collar of detached epidermis Nikolsky's sign is positive, pressure with the finger causing the epidermis to slide off even in areas where the skin appears normal (This sign may also be positive in pemphigus foliaceus, bullous pemphigoid, epidermolysis bullosa, and Ritter's disease [dermatitis exfoliativa neonatorum], and so is far from pathognomonic It is, however, negative in dermatitis herpetiformis, erythema multiforme bullosa, and other bullous conditions)

Pemphigus vulgaris nearly always involves the oral mucosæ, often extensively, and especially the vermilion border of the lips The bulla is seen on section to be epidermal and situated just above the basal layer In the bullous pool and bordering on it, are the acantholytic cells (epidermal cells devoid of intercellular bridges) described by Civatte Tzanck s smear test from the base of a bulla also shows acantholytic epidermal cells In pemphigus vulgaris electrophoretic examination of the bullous fluid, as of the serum, shows a steady decrease in albumin, which with globulin is lost from the denuded areas but unlike globulin is not rapidly regenerated Sodium and chloride are also reduced in proportion to the amount of skin involved The serum-calcium is lowered, but as this involves only the protein-bound fraction, the ionised fraction being unchanged, tetany does not develop A secondary anæmia develops in proportion to the severity of the pemphigus

In pemphigus vegetans, as in pemphigus vulgaris, the initial lesions are flaccid bullæ, but the denuded areas develop hypertrophic granulations—so-called "vegetations"—which extend peripherally These lesions are also sometimes seen in the flexures in cases designated pemphigus vulgaris The mucous membranes are involved in a fashion similar to that in pemphigus vulgaris

In the more benign variant, *pyodermite vegetante*, the primary lesion is a pustule In both forms of pemphigus the difference in disappearance-rates between the normotensive and hypertensive groups could be caused by differences in the placental-pool volume; but as there is no evidence of any difference in volume of maternal blood in the placentæ of normal and of hypertensive patients it seems reasonable to presume that the difference in disappearance-rates of Na^{24} is due to alterations in the rate of placental blood-flow.

---

[1] Lever, W F *Medicine, Baltimore* 1953 32 1

This important technique may have perhaps two principal applications. First, it may throw some light on the problem of postmaturity by means of placental blood-flow studies in successive weeks after full term. Secondly, it may help to answer a question concerning the ætiology of pre-eclampsia. It was Young[3] who first suggested that the placental infarct might be concerned in the ætiology of pre-eclampsia rather than result from it. More recently Bastiaanse and Mastboom,[4] Beker,[5] and others have reported evidence that placental ischæmia may precipitate pre-eclampsia. Zeck and Assali[6] have confirmed that infarcts are significantly commoner with toxæmia than in normal pregnancies, and have shown that acute atherosis of the decidual vessels is commonly associated with toxæmia but is otherwise rare. It would appear, therefore, that the diminished placental blood-flow is due to narrowing of the decidual vessels; but, as Browne and Veall point out, the fact that placental ischæmia was of the same order in their chronic hypertensive patients as in those with pre-eclampsia suggests that the placental ischæmia is the result, rather than the cause, of the hypertension. Theobald[7] has reported successful results from surgical or chemical denervation of the internal iliac arteries as a means of improving the blood-supply to the uterus in cases of recurrent severe pre-eclampsia.

The origin of pre-eclampsia is still unknown; but fundamental research such as that by Browne and Veall will ultimately solve this difficult problem.

BACTEROIDES INFECTIONS

THE bacteroides are anaerobic, gram-negative, non-motile, non-sporing, often pleomorphic bacilli. They comprise a rather heterogeneous group, difficult to classify, and many are more commonly included in the genus fusiformis.[8] They are obligatory parasites which may be found both in disease processes and in the healthy mouth and intestinal tract of man and animals. In the human lower intestine organisms of this group are said to outnumber *Bacterium coli* by a hundredfold or more. Although they occur with such frequency they are seldom isolated in routine bacteriological examinations, for they can grow only with difficulty on artificial media. Brewer's thioglycollate medium is one of the most satisfactory, both for primary isolation and for subsequent subcultures.

Many examples of infections by these organisms have been reported.[9–11] The series described by Fisher and McKusick,[12] however, is of special interest, for it illustrates the value of the newer antibiotics in the treatment of these infections. The 14 cases described give a reasonable cross-section of the types of disease reported by other workers. An empyema developed in 7 cases, lung abscess in 5, liver abscess in 4, abdominal abscesses in 3, brain abscess in 1, mastoiditis in 1, other localised suppurations in 5, and subacute bacterial endocarditis in 2. The infections were often multiple, and in only 5 cases could a specific name be given to the bacteroides isolated. This organism was *Bact. funduliformis* (*Fusiformis necrophorus*) in each instance. An anaerobic streptococcus was found in association with the bacteroides in 5 cases.

The most striking clinical features were the extreme gravity of the illness and the foul-smelling pus in the abscesses. Large numbers of gram-negative bacilli could be seen in the pus, cultures of which became positive only after several days' anaerobic incubation. The white-cell counts were usually raised to about 20,000 per c.mm. and there was a tendency for high counts to persist for some weeks after the infection had been eradicated. The 2 patients who had endocarditis were the only ones in this series who died. The death of one was the result of heart-failure six months after the bacteroides infection had been eliminated by penicillin. Suitable combinations of surgery and antibiotics produced complete cures in all the other patients. The sensitivity of the organisms to antibiotics varied widely; most strains were highly sensitive to aureomycin, rather less so to chloramphenicol, and highly resistant to streptomycin. Susceptibility to penicillin showed the greatest variation, and strains sensitive to concentrations ranging from 0·056 units per ml. to 50 units per ml. were encountered.

THE CONCENTRATION CAMPS

"MILLIONS were killed by direct extermination, but millions more died of famine disease and its complications. Without taking direct murder into account, the average duration of survival in these camps was little over six months." These are the words of a group of Danish doctors,[1] some of whom were among the 6000 people taken from Denmark to concentration camps in Germany during the late war. These doctors now try to describe the social and hygenic conditions in these camps, the famine diseases, and the special difficulties that beset the survivors who returned to Denmark. Every attempt has been made to give factual information about the fate of the Danish inmates and the diseases from which they suffered. The report includes 117 tables, analysing the sufferings of the prisoners; but, as the authors remark, "statistics do not bleed," and so they set out the terrible details.

Tragedy gives men and women an opportunity to bring out their best, and many frightful stories are brightened by heroic efforts in the face of disaster. It was a peculiar evil bent of those who were responsible for organising the concentration camps that they succeeded in making heroism impossible. By mixing up prisoners of every class and nationality and by employing criminals and psychopaths as foremen prisoners, they ensured that lawlessness ruled behind the wires, and they broke up any solidarity among the prisoners. "The shortage of everything, especially food, resulted in an attitude of each one for himself and devil take the hindmost. To this would be added pocket-picking, violence and robbery, all of which were frequent and daily occurrences. Nobody felt safe, everyone being exposed to the danger of assault, particularly during the sparse and badly needed hours of sleep."

The clinical descriptions of the famine diseases are admirable: there are full pictures of hunger cachexia, hunger œdema, and hunger diarrhœa, and these conditions are discussed in the light of the reports of other observers and laboratory workers. Those already familiar with the literature may find little that has not already been reported, except in the long section dealing with the problems that arose after repatriation. Tuberculosis was from five to twelve times as common in those that vegetans the prognosis before the introduction of corticotrophin was usually as bad as in pemphigus vulgaris

Microscopically there are papillomatosis, intra-epidermal, mostly suprabasal, acantholytic bullæ, and intra-epidermal eosinophilic abscesses

The only condition which can give a microscopic appearance identical to pemphigus vulgaris or pemphigus vegetans is the benign familial pemphigus of Gougerot and Hailey-Hailey, believed by some to be a bullous variety of Darier's disease (dyskeratosis follicularis) because of the presence of dyskeratosis and "grains" due to shrinkage of acantholytic cells similar to those seen in Darier's disease The differentiation of this malady from malign pemphigus is usually easy from the family history and the clinical characteristics with predominant involvement of the collar-line, axillæ, groins, and other friction sites

The serum-protein changes are similar in pemphigus vegetans to those found in pemphigus vulgaris, but are less distinct, and the electrolytes are not significantly changed except in pemphigus vegetans malignus

PEMPHIGUS FOLIACEUS

In pemphigus foliaceus the flaccid bullæ are subcorneal and easily ruptured, leaving superficial erosions, with the result that they are rarely seen This malady, then, presents more as an erythematous, oozing, scaling, and crusting eruption, usually starting on the face and chest, and resembling a mildly infective dermatitis or even lupus erythematosus The lesions tend to have serpiginous borders, with very extensive involvement, exfoliative dermatitis is resembled, but in exfoliative dermatitis Nikolsky's sign is negative The scales may show "carpet-tacks" on their undersurfaces The mucosæ and conjunctivæ are rarely involved, and the course, though variable, is usually chronic and not associated with much impairment of the general health in the earlier stages, death, if it occurs, usually results from intercurrent infection

The exact status of pemphigus erythematosus is uncertain There are inconspicuous bullæ and features resembling seborrhœic dermatitis and lupus erythematosus, and an uncertain course which may remain benign or terminate fatally in pemphigus vulgaris or, more particularly, pemphigus foliaceus

BENIGN FORMS OF PEMPHIGUS

In addition to these malign forms of pemphigus there are two conditions, more benign, which have to be differentiated

The first is the condition called by some bullous pemphigoid and by others bullous or senile dermatitis herpetiformis This occurs usually in the elderly, and rarely in children, as itchy tense bullæ, arising either from normal-looking skin or from amongst areas of erythema If the bullæ become broken, the resulting denuded areas do not enlarge but may, on the contrary, tend to heal The bullæ are both small and large and affect in particular the flexor surfaces The erythematous areas are large and often polycyclic, and the whole picture may resemble erythema multiforme The mucosæ are rarely involved, and the vermilion surface of the lips escapes Changes in the serum chemistry resemble those in pemphigus but are slighter The histological features are, however, quite different from true pemphigus, the bullæ being subepidermal and rounded at their edges There is no acantholysis, the epidermal cells being stretched over the bullæ and sometimes undergoing œdema and necrosis above the bulla Nikolsky's sign is positive, but the Tzanck test is negative for acantholytic cells though it shows many inflammatory cells and a few normal looking epithelial cells Bullæ of this kind are also found in dermatitis herpetiformis, herpes gestationis, erythema multiforme, and epidermolysis bullosa The course of this malady is relatively benign except in the very old, in whom it may end fatally Remissions may occur

In benign mucous membrane pemphigoid (pemphigus conjunctivæ, ocular pemphigus) the special features are a predilection for the oral mucosæ and conjunctivæ and a pronounced tendency to scarring, the bullæ being subepidermal and associated with a great deal of inflammatory reaction Scarring of the palpebral fissures or of the mouth may occur, and adhesions between the eyeball and the lids may limit movements of the eye Xerosis, corneal ulceration, or the development of an opaque horny membrane over the cornea may lead to blindness The disease may be confined to the mouth for a considerable time before other areas are affected, and scarring is much less pronounced here than on the eyes About half the patients have skin lesions—either recurrent bullæ, healing without atrophy, or red areas with flaccid bullæ going on to denudation and smooth atrophic scarring The course is usually benign, apart from the serious ocular damage

TREATMENT

Among hypotheses on the causation of these mysterious maladies, that most favoured today is interference with some enzyme activity in the skin A viral or bacterial cause has not been substantiated

Despite ignorance about the nature of pemphigus and pemphigoid eruptions, one thing is clear their control has been revolutionised by the introduction of corticotrophin In the past, arsenic, suramin, and vitamin D were used, with uncertain effect, and blood transfusions have been given in an attempt to bring about a remission Antibiotic drugs, particularly aureomycin and chloramphenicol, have been reported to cause remissions in a proportion of cases when first used, but not subsequently

In 1940, Talbott et al [2] reported the value of adrenal cortical extract in the control of pemphigus All types of pemphigus and pemphigoid respond well to corticotrophin or cortisone provided the dosage is adequate, but the beneficial effect is temporary, and if relapse is to be prevented the drugs must be given either continuously with a maintenance dose or in repeated courses

Against continuous treatment are the many unpleasant side effects of corticotrophin—in particular, fluid retention leading to cardiac decompensation, low potassium alkalosis, reactivation of old pulmonary tuberculosis or of a peptic ulcer, psychoses, and severe infections To avert some of these possible side effects, a low sodium chloride intake, prophylactic potassium chloride 2–6 g daily, and the administration of an antibiotic are indicated

With regard to dosage, Lever believes that this should be adjusted according to the clinical response, and that eosinophil-counts and 17-ketosteroid estimations are of secondary importance

The usual initial dose of corticotrophin is up to 40 mg intravenously, given over an 8 hour period, the amount depending on the severity of the case, 40 mg intravenously is equivalent to 280 mg of corticotrophin, or to 700 mg of cortisone, intramuscularly

A reduced daily dose of 20 mg should be maintained for several weeks after the lesions have healed Then follows the difficult decision whether to adopt continuous or intermittent dosage, and whether to give corticotrophin or cortisone Cortisone, when it can be more readily produced, should prove the drug of choice for ambulant patients once the condition has been brought under control returned as in the corresponding age-groups of the male population of Copenhagen at that time. In addition to the great risk of infection in the camps, evidence shows that the low calorie-intake itself probably impaired the processes of immunity. No special form of "concentration-camp tuberculosis" was found, but the prognosis for the repatriated prisoners seemed to be better than might have been expected. On the other hand, psychological reablement was often slow. Restlessness and an inability to concentrate retarded the return to normal social life and working activities. The dissatisfaction of the active members of the resistance movement with the subsequent political developments may have contributed to the persistence of these symptoms.

---

[2] Talbott J H, Lever, W F Consolazio, W V *J invest Derm* 1940, 3 31

The Danes remark that they had been singularly ill-equipped by their medical education to deal with famine diseases. We may fairly hope that the evils of the concentration camps will never come again; but, in the present state of world agricultural and food economy, it is certain, even in the most optimistic outlook, that many of the world's doctors will have to deal with hunger cachexia, œdema, and diarrhœa. Among their many commitments medical teachers could usefully devote a little more time to these diseases, and this excellent Danish report would help them to do so.

AMŒBICIDES

In the last few years so many new amœbicides have appeared that their comparative evaluation has been somewhat difficult. Emetine, carbarsone, chiniofon, and di-iodohydroxyquinoline ('Diodoquin') have been followed in quick succession by chloroquine, bismuth glycolylarsanilate ('Milibis'), and the antibiotics—chloramphenicol, aureomycin, and terramycin (oxytetracycline). Normally it is difficult to get enough patients for the trial of a single amœbicide; and to keep them under observation long enough for repeated examinations of the stools, to see if relapse ensues after recovery from the acute condition, is even more difficult. An unusual opportunity to observe the response of acute amœbic dysentery to therapy with several of the new amœbicides arose recently in a United Nations prisoner-of-war camp in Korea, where Martin and his colleagues,[1] of the U.S. Medical Services, in collaboration with members of the U.S. Public Health Service, treated 644 cases. The criteria for diagnosis were diarrhœa, abdominal tenderness and pain, blood and mucus in the stools, lesions of the colon visible on sigmoidoscopy, and trophozoites of *Entamœba histolytica* in the stools. The number of cases sufficed for comparative trials of twelve drugs or combinations of drugs. Saline smears of stool specimens were examined for *E. histolytica* on the first, second, fourth, and sixth days and weekly thereafter for six weeks; sigmoidoscopy was done every week. The criteria of cure were disappearance of diarrhœa and exudate in the stools, absence of trophozoites or cysts of *E. histolytica*, normal sigmoidoscopic appearances, and freedom from symptoms. Vegas[2] carried out a similar study on civilians at Caracas, Venezuela. He treated, and followed up for six to twenty-four months, 264 patients with amœbic dysentery, which he estimates to be present in about 9% of the middle and upper classes in Caracas. With such a large number of patients Vegas was also able to compare the clinical effectiveness of a number of amœbicides.

Both Vegas and the North American workers failed to confirm the early enthusiastic reports on the value of aureomycin in amœbiasis; the initial results were good, but the relapse-rate was high. In fact none of the drugs given alone prevented relapse. Emetine, carbarsone, aureomycin, and chiniofon gave a reasonably good initial response, but there were many relapses. Chloramphenicol was disappointing in the hands of both groups of workers. Terramycin gave the best results of any one drug, but its side-effects after long use—diarrhœa, pruritus ani, and abdominal cramps—and its high cost were serious drawbacks. Vegas considers that bismuth glycolylarsanilate is one of the best amœbicides. Even so, over 50% of the patients he treated with this drug were passing cysts again one year after treatment.

Amœbiasis may not be a purely localised intestinal infection but a systemic disease as well. If this is so, a combination of a relatively insoluble amœbicide, acting only in the gut, with one that is readily absorbed might be expected to give the best results. In the hands of Vegas a combination of the non-absorbable arsenical, bismuth glycolylarsanilate, with the highly absorbable chloroquine proved more effective than any single amœbicide or combination of amœbicides. Martin and his colleagues observed a good initial response with a combination of bismuth glycolylarsanilate and chloroquine; but the relapse-rate was high. They obtained the best results with terramycin, which is absorbed, combined with any of the standard amœbicides, such as emetine, carbarsone, chiniofon, and chloroquine. Elsdon-Dew et al.[3] also obtained good results by combining an antibiotic with one of the established amœbicides. The antibiotics act not only on the amœbæ but on associated and probably symbiotic bacterial flora in the gut. Wilmot et al.[4] have shown that antibiotics have little or no effect on amœbic liver abscess, where there is no confusion between antibacterial and anti-amœbic effect. This suggests that in amœbic dysentery antibiotics act largely on the symbiotic bacteria rather than directly on the amœbæ. It therefore seems that in treating amœbic dysentery we should aim at killing one bird with two stones—that is, with an amœbicide and a drug acting on symbiotic organisms in the gut.

SINGLE VENTRICLE WITH PULMONARY STENOSIS

When the ventricular septum has failed to develop there is a single ventricular cavity into which the auriculoventricular valves open and from which the aorta and pulmonary artery, usually transposed, arise. The patient usually dies in infancy or childhood but may survive to middle age. Campbell et al.[5] describe six cases of single ventricle with pulmonary stenosis, and a seventh of single ventricle with pulmonary atresia; and they also review 85 reported cases of single ventricle.

Their cases were not diagnosed during life; and Campbell et al. show that such cases are liable to be mistaken for Fallot's tetrad. The structural defects in the two conditions are similar, the main difference being that in one the interventricular septum is incomplete and in the other absent. Likewise the symptoms and physical signs may be exactly the same in the two conditions. In all seven hearts there were other defects in the heart chambers, valves, and great vessels; anomalous pulmonary veins were common. The plain radiographic appearances were not diagnostic, but angiocardiography showed a rapid spread of dye to the left side of the heart, from which Campbell et al. think a diagnosis of common ventricle might be suspected. The electrocardiogram (E.C.G.) of these cases is of especial interest, as it is a problem where, in the absence of the interventricular septum, the conducting bundle and its branches lie. In each case the E.C.G. showed the pattern seen in left ventricular preponderance or hypertrophy; the auriculoventricular conduction-time, judged by the P–R interval, seems generally to have been within normal limits for the ages of the patients; but one E.C.G. seems

CORONATION HONOURS

The list of honours published on June 1 contains the names of the following members of the medical profession

K C M G

Lieut General Sir **James Bennett Hance**, K C I E O B E, M D Camb, F.R C S E
Medical adviser to the Secretary of State for Commonwealth Relations, and President of the Medical Board, Commonwealth Relations Office

K B E (Military)

Air Marshal **James MacConnell Kilpatrick** C B, O B E, M B Belf, Q H P
Director general, R A F Medical Services

K.B E (Civil)

Francis Gordon Bell, M C, M D Edin, F R C S
Formerly professor of surgery, University of Otago

Knights Bachelor

The Hon **Nicholas Attygalle**, F R C S, F R C O G
President of the Senate of Ceylon
For services to medicine

David Campbell, M C, M D Glasg F R F P S
President of the General Medical Council, regius professor of materia medica and therapeutics, University of Aberdeen

Francis Martin Rouse Walshe, O B E, M D, D SC Lond, F R C P F R S
President of the Royal Society of Medicine, consulting physician, University College Hospital, and the National Hospital, Queen Square

C B (Military)

Major General **Joseph Clinton Collins**, C B E, M R C S, Q H S

Major General **Frederick Knowles Escritt**, O B E, M R C S, Q H S

C M G

Philip Stanley Foster, M B N Z, F R C S, F.R.A C S
Consulting surgeon, Christchurch Hospital, New Zealand, chairman, Medical Council of New Zealand

George Macdonald, M D Lpool, M R C P
Professor of tropical hygiene, University of London, and director of the Ross Institute of Tropical Hygiene

C V O

John Nigel Loring, M.R C S
Apothecary to Her Majesty's Household

C B E (Military)

Colonel **Kenneth Barron Fraser**, CH M Sydney, F.R A C S, R.A.A M C
Visiting senior surgeon, Children's Hospital, Brisbane

Air Commodore **Patrick Brunton Lee Potter**, O B E, M D Sheff, R.A F

Air Commodore **Frederick Elvy Lipscomb**, M R C S, Q H.P, R.A.F

Surgeon Captain **Samuel Gerald Weldon**, M B Dubl, R N

Colonel **Frederick William Whiteman**, O B E, M B Glasg, Pakistan Armed Forces Medical Services

C B E (Civil)

William George Barnard, F.R C.P
Professor of pathology in the University of London at St Thomas's Hospital

Gilbert Brown, M.B Lpool, F F.A R C S
Honorary consulting anæsthetist, Adelaide Hospital, South Australia

Thomas Morris Davies, M.R C S
Deputy director general of Medical Services, Ministry of Pensions

Alan Taylor Howell, M B Camb
Director of Medical Services, Tanganyika

William Leslie, M C, M B Lond
For political and public services in Cornwall

Archibald Daniel Marston, F R C S, F F A R C S
Lately dean of the Faculty of Anæsthetists, Royal College of Surgeons

Arnold Ashley Miles, M D Camb, F R C P
Director of the Lister Institute of Preventive Medicine

Gilbert Innes Strachan, M D Glasg, F R C P, F R C S, F R C O G
For political and public services, and for services as professor of obstetrics and gynæcology, University of Wales

Richard Robertson Trail, M C, M D Aberd, F R C P
Medical director, Papworth and Enham Alamein Village Settlements for the Tuberculous

M V O (4th class)

James Lawrence Bunting Ansell, M R C S
Surgeon Apothecary to the Household at Sandringham

O B E (Military)

Surgeon Commander **John Mansel Reese**, M R C S, R.N

O B E (Civil)

Francis Ward Allinson, M B Lond, F R C S
Professor of surgery, Medical College Hospital, Dacca, Bengal

Charles Anthony Boucher, D M Oxfd
Medical officer, Ministry of Health

Cecil Burnham, M B Edin, F.R.C S E
Lately commandant, Star and Garter Home for Disabled Soldiers, Sailors, and Airmen, Richmond, Surrey

William John Hughes Butterfield, M D Johns Hopkins, B M Oxfd, M R C.P
Member of the scientific staff of the Medical Research Council

Richard Alexander Seymour Cory, M B Brist
Senior medical officer, King George V Jubilee Memorial Sanatorium, Liguanea, Jamaica

Kenneth John Grant, M B Glasg
Medical officer of health, Great Yarmouth
For services during recent floods in the Eastern counties

Eben Stuart Burt Hamilton, M C, M B Edin., F R C S E
Commissioner, Duke of Lancaster's District, St John Ambulance Brigade

Albert Joseph Hawe M D Lpool, F R C.P
Senior specialist, Gold Coast

Gordon King, F R C S, F.R C O G
Professor of obstetrics and gynæcology, University of Hong-Kong

James Sanderson McGregor, M D Glasg
Medical superintendent, Saxondale Hospital, Radcliffe-on Trent, psychiatrist, Nottingham General Hospital

Colonel **William Joseph Moody**, M B Camb, F.R C S E, I M S retd
Lately medical adviser to the British Political Resident, and chief quarantine medical officer, Persian Gulf

George Rankine, M C, M.B Edin
General practitioner, Dundee

Sarah Anderson Jameson Rankine, M B Glasg
Medical officer in charge of St Margaret's Hospital, Poona, Bombay

Henry Richards, M B Lond
Assistant director (Public Health), Sudan Government

George Robertson Ross, M B, PH.D St And
A member of the Public Services Board, Southern Rhodesia

Emrys Cadwaladr Thomas, L.R C P E
Director, Victoria Hospital, Damascus

John Duncan White, M B Edin
Director, Radiodiagnostic Department, Hammersmith Hospital, London

Thomas Macfarlane Wilks, M B E, M R C S
Area commissioner, St John Ambulance Brigade, London.
For services during recent floods in the Eastern counties.

Donald Bagster Wilson, M D
Director, East Africa Malaria Unit

to show ventricular pre-excitation, and this and one other show what could be regarded as partial right bundle-branch block.

The diagnosis of single ventricle in life, apart from its academic interest, is important from the point of view of surgical treatment. The prognosis is said to be better when pulmonary stenosis is present, and therefore no attempt should be made to relieve this. On the other hand Campbell et al. recommend that subclavian-pulmonary anastomosis should be done when there is considerable cyanosis and disability, although they found that in their own proved cases this had not been beneficial.

BARBITURATES AND ALCOHOL

Two recent deaths from barbiturate poisoning have attracted considerable attention.[1] [2] In each instance the total quantity of the drug taken, as estimated by post-mortem examination, was scarcely more than the maximum therapeutic dose—it was certainly nowhere near the amount usually regarded as lethal. But, in both cases, a small quantity of alcohol had apparently been taken about the same time as the barbiturate, and this, above all, was regarded as the sinister complication. At one inquest the pathologist's view is said to have been that "even a minute quantity of alcohol would speed the action of the drug"; and at the other a psychiatrist is quoted as saying that "occurrences of this kind are constantly happening. There have been three or four accidental occurrences in the past ten days to my knowledge." In view of such statements the coroners concerned, quite naturally, issued stern warnings to doctors and to the public.

But if the danger is as great as this, it is strange that so little has been said about it in the past. It may be mentioned to students, but with no great emphasis, and there must be thousands of doctors in practice who know nothing of this possibility of the barbiturates. Moreover, considering that barbiturates are so freely dispensed under the National Health Service[3] and that most people in this country are not teetotallers, it is surprising that deaths from this cause have not been more numerous. In the U.S.A. alcohol and barbiturates are also consumed in large quantities, but again few deaths have been attributed to their combined action.

In 1943 Jetter and McLean[4] investigated this very question; for, as they observed, "the possibility of synergism between alcohol and a barbiturate is a matter of considerable practical as well as theoretic interest." In rats they demonstrated a definite synergism between the two drugs when given in sublethal doses. But even when both drugs were given together, each in half the maximum sublethal dose, only 1 out of 6 rats died. Clearly, there was a synergistic effect, but that is a very different matter from potentiation. Jetter and McLean also cited 3 examples of fatal poisoning in man; in these cases it was clear that one drug alone could not have caused death. But the total quantities involved were very great; and one victim "was addicted to both alcohol and barbital." Again, with mice and dogs, Ramsey and Haag[5] found further evidence of synergism, but none of potentiation; and the concentration reached in the body by the two drugs was no different whether they were given alone or together. Pharmacologically, both alcohol and the barbiturates are depressants of the central nervous system, so a synergistic action is not unlikely; but, as we have said, that is a far cry from the potentiation necessary to turn innocuous individual doses into a fatal combination.

The dangers of giving barbiturates to those who take alcohol have probably been overstated. On the other hand, of course, barbiturates are in themselves deadly drugs, which are perhaps used too lightly today. Moreover, their effects vary considerably from one person to another, not only in the amount needed for a given hypnotic effect, but also in the dose that proves fatal. And in those who regularly take barbiturates a further factor may have to be considered, for Brodie[6] has shown that the action of thiopentone becomes progressively longer with repeated doses, even though the dose remains the same. The drug, it seems, is taken up by the fatty tissues and later released into the body-fluids; and a similar thing is possible with the longer-acting barbiturates. If so, the cumulative effect may be serious and a disastrous combination with alcohol easier to explain. But the fact remains that thousands of people take barbiturates in the usual doses, even more drink alcohol in one form or another, and yet few deaths have been proved to be due to the two drugs in combination. To give an extreme example, patients with inoperable cancers are often given generous amounts of wines and spirits and large doses of barbiturates at the same time; but they seldom die of alcohol-barbiturate poisoning.

If the possibilities are really as serious as some of the evidence at these inquests suggests, then the matter demands urgent inquiry. But it may well be that these two tragedies are examples of particular idiosyncrasies, serious enough in themselves, but no basis for a general alarm.

VACCINATION AND ECZEMA

THE death of a doctor's 5-month-old baby from generalised vaccinia on the eczematous skin (eczema vaccinatum) in a district where virulent cases of smallpox had occurred,[7] emphasises the occasional tragedy which the practice of vaccination, like many other normally harmless medical procedures, entails.

It is not easy to present to a sedulously inquiring parent a balanced view of the substantial advantage likely to accrue to the child and the community from successful vaccination when the minute risk associated with the operation must be mentioned and accepted. But guiding rules are now fairly clear. Vaccination should preferably be performed in infancy during a stabilised period of good health, and should unhesitatingly be postponed if the child is ailing in any way, and especially if suffering from infantile eczema, tuberculous primary complex, syphilis, or any febrile attack or septic condition of the skin. Similarly, any infant with eczema should be rigidly isolated from any person recently vaccinated. The vaccination lesion should not be looked on as simply a localised sore, but rather as a local lesion accompanied by a viræmia which can set up metastases in any devitalised area of skin or elsewhere. Infantile eczema, even if mild at the time, is perhaps the most obvious contra-indication to vaccination in this country; for a large area of skin sown with numerous vaccinal lesions can be rapidly fatal unless, perhaps, the secondary septic intoxication is at once overcome by effective antibiotic treatment. This rule is generally valid even when there is smallpox in the district; for, with few exceptions, the risk of acquiring smallpox will be much less than the very substantial risk of developing dangerous eczema vaccinatum. In cases of infantile eczema, vaccination should preferably be postponed until the skin has been completely normal for at least a year. This generally means postponement to the pre-school age and a consequent slight increase of the minute risk of postvaccinal encephalitis. But this danger is so small as to be negligible compared with the hazards of eczema vaccinatum.

THE death was announced last week of Dr. H. M. LESTER, director of medical services in Malaya.

PHYSICAL TREATMENT AT THE BRITISH SPAS

AT the suggestion and under the direction of the medical committee of the British Spas Federation, an investigation of the effect of physical treatment, including hydrotherapy, on rheumatic cases at a number of centres has been carried out The following information has been supplied to us by Lord Horder and Dr G D Kersley, respectively chairman and secretary of the committee

It was realised from the start that a completely controlled therapeutic trial was not possible, because it was impossible to rule out psychological influences Such factors must, however, play their part in the effect of therapy, and every effort has been made to give genuine clinical assessments Only typical cases of rheumatoid arthritis, osteo-arthritis, and fibrositis were investigated, and no parenteral therapy was used during the period of observation Cases were assessed before treatment, directly after treatment—i e , in three to six weeks—and again three months later

128 cases of rheumatoid arthritis, 227 of osteo arthritis, and 112 of fibrositis were followed up in this way, and the results were statistically analysed by Mr E Lewis Faning, D SC , of Cardiff University Degree of pain on movement or at rest, swelling, tenderness, and range of movement were numerically recorded, together with age and sex, on a special pro forma drawn up for the purpose No points of especial interest were forthcoming from analysis of age and sex groups, but the general effect of treatment, both immediate and after three months, is of importance and accords well with clinical impressions

In the rheumatoid arthritis group of 128 patients approximately half, it is stated, appeared to derive significant immediate benefit, and a slightly larger number were definitely improved on a three months' review This applied both to a more "active" and to a more "quiescent" subgroup In the former 68% showed decrease in tenderness and 54% in swelling of the worst affected joint, but only 36% had reduction of pain at rest Only 1 patient appeared to be worse

In the group of 227 osteo arthritics, approximately two thirds stated that they had less pain and half had increase in range of movement After three months the result was slightly less good, with 62% stating that they had less pain than before treatment

In the group of 112 "fibrositis," again two thirds claimed improvement, and the result of assessment three months later showed neither increase nor decrease in this benefit figure

In England Now

A Running Commentary by Peripatetic Correspondents

Westminster Abbey But an Abbey transformed into a theatre—and this word is entirely appropriate, since the part of the Abbey where the Coronation ceremonies take place is termed the theatre, and the seating of the whole building has been redesigned so that all present may see some part of the service with their own eyes, though many will have seen less than those who watched through the eyes of the television cameras What then did we who were there see ? We saw the colours , the blue of the carpet in the nave repeated in the hangings in front of the lower tiers of seats and again in front of the gallery, and, filling the seats like a human flower garden, the scarlet of the robes of the aldermen of the City of London, the scarlets, blues, and golds of the full-dress uniforms and the decorated greens golds, and blues of costumes from the far East And beneath the gilded hanging chandeliers and the floodlights which diffused a sunny radiance from the ceiling glowed the robes of the peers and peeresses, the copes of the clergy, and the cassocks of the choirboys , and the standards carried by the standard-bearers , and the diamonds in the tiaras and the sceptre and the Imperial Crown itself shone and glittered

And we saw the Queen, not through some mechanical medium but face to face , and for at least one spectator the most moving moment was not the crowning itself but her first appearance, when after all the processional panoply she entered through the west door and moved slowly up the nave, her hands clasped with palms upwards before her, and her face that of one dedicated

But we in the Abbey saw also the unseen "Here's an acre sown indeed with the richest, royal'st seed,' wrote Beaumont *On the Tombs in Westminster Abbey*, and, though he went on to moralise in conventional fashion on the mortality of kings, his insight as a poet served him better perhaps than he knew For the history enshrined in the Abbey is indeed the seed from which our present greatness has sprung Its roots are in the past, and from these it must draw its nourishment, but its leaves spread in the sunshine of today, and if the present lives upon the past it is equally true that the past derives its vitality from the present Orders of knighthood and the heraldry which emblazons their pomp would soon become an empty show if the chivalry which gave them birth could find no expression in the England of today and feel no challenge in the quests of the modern world So a Coronation is a rebirth, a new life growing from the 'acre sown indeed with the richest royal'st seed"

And the life of the nation thus renewed comprehends far more than merely government, administration, and defence Prominent though these features were in the processions, it was the whole nation which was represented in the Abbey, and represented not only by living men and women but also by an unseen cloud of witnesses from the past and by that simple representative of the common people, the Unknown Warrior, whose tomb divided every procession entering and leaving the Abbey

So the past and the present intermingled and not only were the living moved by the ceremony they witnessed but it seemed that the bones of that stout old monarchist, Samuel Johnson, and the dust that was once Thomas Hardy, ironical but compassionate commentator upon dynasts were fondly stirred by the fanfare of trumpets and the fresh boys' voices shouting *Vivat Regina, vivat Regina Elizabetha !*

* * *

The damp but enthusiastic crowds who waited on the stands and pavements outside the Abbey were rewarded by a magnificent military parade, but it was really the coaches that made it a royal occasion We all began by being indebted to the peers who bravely drove to Westminster in all the flunkeyed splendour of their family equipages The opening of the procession itself was entrusted to an experienced annual performer—the Lord Mayor's coach burnished and resplendent and guarded by pikemen The Speaker's coach accompanied by attendants in green velvet, rounded Parliament Square with a swinging motion which might well have

Before Our Time

RECORD OF THE CASE *

Sir JOHN CHARLES
M.D. Durh., F.R.C.P., D.P.H.
CHIEF MEDICAL OFFICER TO THE MINISTRY OF HEALTH

AT 8 o'clock on the evening of Thursday, October 24, 1867, Wagner scored the final bars of *Die Meistersinger*, inscribed the time and date, and laid down his pen.

Without any comparable marking of the chronology, but just as conclusively, a Theban scribe set aside his pen 3600 years ago, "in the middle of a line, in the middle of a sentence, in the middle of a word." His task had been the copying of an old surgical treatise, written in its primordial form at least a thousand years earlier.

Five hundred years before this scribe began his labours, a commentator had added to the original text an interpretation of some of its archaic words and phrases, and these glosses too were transcribed on to the roll of reed paper, which we know as the Edwin Smith Surgical Papyrus.

The treatise was in essence a catalogue of 48 surgical cases, all males, and many of them warriors. The descriptions of the surgical experiences of those patients are, in the conventional sense of the words, our earliest medical records. The grouping of the 48 cases suggests that they were part of a larger collection. Commencing with the head and skull, they next include the neck, clavicles, humerus, sternum, and spinal column—and then cease abruptly. The logic of the descriptive scheme envisages a commentary on the surgery of the thorax, abdomen, and lower members. But some event or person interrupted the work of the scribe. He evidently contemplated the resumption of his copying, for a stretch of 31 inches of virgin papyrus was left between his unfinished task and the engrossing of a collection of incantations and medicinal and cosmetic recipes.

Not only was there order and method in the planning of the treatise, but the presentation of each case conformed to a simple pattern. First there came an identification of the case; next a statement of the examination; then a diagnosis and a tentative prognosis in three ascending degrees of severity—an ailment that could be treated, an ailment that could be contended with, an ailment not suitable for treatment. Finally, the treatment was prescribed. Here is the record of a simple case—a broken nose.

> If thou examinest a man having a break in the column of his nose, his nose being disfigured, and a depression being in it, while the swelling that is on it protrudes, and he has discharged blood from both his nostrils—thou shouldst say concerning him "an ailment which I will treat."
>
> Thou shouldst cleanse it for him with two plugs of linen. Thou shouldst place two other plugs of linen saturated with grease inside of his two nostrils. Thou shouldst put him at his mooring stakes until the swelling is reduced. Thou shouldst apply for him stiff rolls of linen by which his nose is held fast. Thou shouldst treat him afterwards with grease, honey and lint every day until he recovers.

The hand of the gloss-writer has explained the unusual simile—"put him at his mooring stakes" means putting him on his customary diet, without administering a prescription.

Of the 48 cases described, no more than 15 were assigned to the category of the hopeless, and in 1 instance only did the practitioner substitute magic and incantations for surgery.

THE HIPPOCRATIC CORPUS

Twelve hundred years after the unfinished business of the Edwin Smith Surgical Papyrus, there was accumulated in Greece a very different collection of medical and epidemiological knowledge. This corpus of writings, a veritable library of treatises, aphorisms, case-histories, and the like, is associated with the name of Hippocrates. How much is attributable to Hippocrates himself one cannot now say, but the collection represents the thoughts and experiences of tough minds and keen observers.

Here again we have a group of medical records to study, and on this occasion surgery is joined by medicine and midwifery and the patients are freemen and slaves, men, women and children often identified by name or domicile. The celebrated clinical picture-gallery of the first and third books of *Epidemics* displays 42 cases, 25 of them fatal. They are preceded by brisk, critical commentaries, the so-called constitutions, which discuss in general terms the meteorological conditions of the respective seasons, the epidemic disorders which were prevalent, their trends and features. So we find it recorded that in the spring of some undatable year

> Many had swellings beside one ear, or both ears, in most cases unattended with fever, so that confinement to bed was unnecessary. In some cases there was slight heat, but in all the swellings subsided without causing harm. . . . This was the character of them—flabby, big, spreading with neither inflammation nor pain. . . . The sufferers were youths, young men, and men in their prime, usually those who frequented the wrestling school and gymnasia. Few women were attacked.

Then follow in no particular order and in varying detail the clinical histories and descriptions of the patients.

Lastly, as an appendix to the majority of cases in the third book of *Epidemics*, we encounter a sort of registrar's summary, a synoptic line of a few Greek capital letters, which gives the duration, outcome, and character—that is the operative word—of the disease. Seven such capitals epitomised the death from fever and diarrhœa of a woman who seven days previously had had a miscarriage.

The 42 case-histories of those two books of *Epidemics* have been described as the most remarkable product of Greek science. They differ markedly from the records of the Edwin Smith papyrus. Their breadth of clinical interest is greater; the presentation of the case is fuller; the statement of personal and social detail is more elaborate. But their outstanding distinction is to be seen in the cool day-by-day study of the progress of the pathological phenomena in the body of the patient. Often the phrases which record these changes have caught for all time the physiognomy of disease or the prolegomena of dissolution. Oddly enough, in comparison with Egyptian practice, there is a virtual omission of any reference to treatment.

That combination of calm observation and apparent implicit reliance on the curative powers of Nature has given rise to the suggestion that the Hippocratic case-book is little more than a "meditation upon death." Such comment is not altogether fair, because in another of the books of the corpus, the *Regimen in Acute Disease*, the cardinal remedies are adequately described.

Amongst the diseases met with are examples of those protean Mediterranean malarial fevers, of puerperal and wound infections, of the pneumonias and dysenteries, and of several strange delirious states which cannot be precisely identified. Here are two specimens of these records, as brief and succinct as any in the collection:

> (*a*) Crito, in Thasos, while walking about, was seized with a violent pain in the great toe. He took to bed the same day with shivering and nausea; regained a little warmth; at night was delirious.
>
> Second day. Swelling of the whole foot, which was rather red about the ankle, and distended; black blisters; acute fever; mad delirium. Alvine discharges unmixed, bilious and rather frequent. He died on the second day from the commencement.

> (*b*) Another woman, after a miscarriage about the fifth month, the wife of Hicetas, was seized with fever. At the beginning she had alternations of coma and sleeplessness; pain in the loins; heaviness in the head.

---

* Opening address at the First International Congress on Medical Records. London, Sept. 8, 1952.

made a longer journey trying to its occupants. The Colonial rulers rode in open carriages which allowed us to admire the vivid and delicate colours of their robes and their strange and beautiful headdresses. Salote, the genial Queen of Tonga, in her petunia cloak was the crowd's favourite. The prime ministers and the princes and princesses of the blood royal were in closed but elegant carriages. The Queen Mother and Princess Margaret in the glass Irish Coach prepared us for the splendours of the State Coach itself carrying the Queen to her crowning with flowers on her lap and carrying her back to her people with the orb and the sceptre in her hands.

* * *

Well, of course, Selfridges have their horse, the crowns swing over The Mall, the emblematic guardsmen march down Whitehall, the pink roses of Regent Street have promoted as lively a discussion as the red and white ones, the City is tented in white streamers, the Strand has hopefully erected a maypole. All these in their way are part of the Coronation celebrations. But on none of them has more loving care been lavished than on those in our cul de-sac. These were put up on pre-Coronation Thursday by Mr Morganti, the greengrocer, Mr Pollak, the shoemaker, Mr Bernstein, the tailor, young Jack Morganti and a large Alsatian dog with the help of a ladder borrowed from the workmen who are demolishing a house on the bombed site at the corner. Mrs Morganti had run the Union Jack through some nice hot suds, and the colours had come up lovely, though perhaps it had shrunk a little. Anyhow it proved too small to stretch from the lamppost to the barber's shop. But Mr Bernstein resourcefully made a small seam along one edge through which he ran a piece of white tape. Thus informally suspended it has taken the wind to everybody's satisfaction. Surely it is quite a compliment to the Queen that all these Ruths, instead of moping about among alien corn, have been briskly nailing up bunting.

* * *

To the conscientious doctor there is always a snag about taking even a Coronation weekend off. We can take four weeks off at a stretch and the fates are with us. Our patients remain alive. They don't develop obscure surgical conditions, go into comas, have stillborn babies, or depart en bloc to the doctor across the road. They behave, in fact, as normal healthy human beings. But let me take a weekend off, or worse still Friday to Sunday night, and everything happens. Supposedly healthy patients choose that time for dying suddenly. They develop acute appendices, they have heart attacks, they gas themselves, they go into premature labour. But on Monday morning everything drops back to normal. It doesn't only happen to me. My partner complains bitterly that it happens to her too, and other colleagues say the same. It almost seems that it is against Nature for a G.P. to take a weekend off. If our patients really benefit by our taking long holidays and are worse when we take short ones, it certainly won't be too unpleasant to pander to their fads for once.

* * *

I was sitting by the window looking out on lovely country in blazing sunshine while the doctor examined my host's small son. Lazily I listened with half an ear to the list of symptoms: high temperature, a terrible cough, a flush, pain in the back of the neck but no stiffness. What would the diagnosis be, I wondered. "I suppose it's alotothis again," said the father. The doctor nodded, shook down his thermometer, and wrote out a prescription. Alotothis? I hastily repeated to myself cyanosis, halitosis and all the familiar words of that family, but I was still baffled. I did not like to betray my ignorance so I asked no questions. The child was better next day, but the infection went through the house with a 3-day interval between cases.

When I was back in town I developed the mysterious disease myself and called in a colleague. I told him my symptoms and then added with pride: "I can tell you what the diagnosis is." But he was not listening. "You know," he said, "there's a lot of this about."

Letters to the Editor

JUNIOR RESIDENT STAFF

SIR,—As long as the hospital administrator regards the junior resident staff as cheap labour, and no more, so long will the shortage in provincial hospitals continue. A resident may expect to receive as well as to give: married quarters and television sets are no substitute for supervision, instruction, and the opportunity for self-improvement. The shortage in the United States is at least as serious as it is here, and a committee of the American Medical Association has recently issued a report which deserves reading.[1] Probably the most important statement was a reaffirmation of one which is embodied in the association's "essentials of an approved internship": to be suitable for an internship a hospital must be one in which "the educational benefits to the intern are considered of paramount importance, with the service benefits to the hospital of secondary significance."

London W 1 FILIUS TERRÆ

SIR,—There are those who object to the National Health Service being termed an industry; but from the article by Mr Hurst and his colleagues (May 23) it would seem that the outlook on working hours and working conditions which pervades industry has now permeated that service.

Speaking of possible remedies to deal with the apparent shortage of junior doctors in hospitals the writers say: "It seems certain that doctors will not go back to the earlier unsatisfactory conditions of long working hours; nor should they be expected to do so." When I was a young houseman at Westminster Hospital I never knew that time existed. I was happy round the clock even if that meant little or no sleep, no leisure, and no recreation—which often was the case. My total remuneration was £1 a week and all found, including laundry, plus the odd theatre ticket from the matron's office.

Such phrases as 'working hours' and 'unsatisfactory conditions'' never entered our thoughts—still less our vocabulary. We were supremely happy to find ourselves on the threshold of our chosen career.

Public Health Department,
Cardiff J GREENWOOD WILSON

SIR,—I wonder whether Mr Hurst and his colleagues have inquired into the views of the junior medical staff. Their article (May 23) suggests lack of understanding of the doctor's side of the problem.

In the first place, few medical men who have competed for posts in the better-known hospitals or in general practice, would agree that there is a shortage of doctors.

In selecting a hospital post, two factors are usually considered: (1) the experience to be obtained or the value of the post as a background for obtaining further posts; and (2) the attractiveness of the hospital—its atmosphere, accommodation, food, &c. It is perhaps to be deplored that the posts offering the best experience often have the least "name value" in applications for further posts; but that is not the administrator's problem. What does concern him is the resentment felt by many residents at the petty restrictions, legislation, charges, economies, and so on, so often imposed upon them by the "nine-till-five" staff. The long hours and extra duties of the houseman are always taken for granted, and only rarely is anything done to cheer up his quarters or to improve his food. More often thanks for his twenty-four hours' service are expressed in the form of a bill for 2*d*. for a cup of coffee given to a friend.

From my own experience I should say that what is chiefly needed is a change in the attitude of the administrative staff towards residents.

EX-HOUSE-OFFICER

---

[1] J. *Amer. med. Ass.* 1953, 151, 499.

Second day. Bowels disordered with scanty, thin stools, which at first were uncompounded.

Third day. Stools more copious and worse; no sleep at night.

Fourth day. Delirium; fears; depression. Squinting of the right eye; slight cold sweat about the head; extremities cold.

Fifth day. General exacerbation; much wandering, with rapid recovery of reason; no thirst; no sleep; stools copious and unfavourable throughout; urine scanty, thin and blackish; extremities cold and rather livid.

Sixth day. Same symptoms.

Seventh day. Death.

The shorthand epitome of this second case requires eight Greek capital letters.

These are crisp, comprehensive narratives, composed by an alert eye-witness. Medical literature, except in rare examples, shows nothing like them for the next 1700 years.

THE MIDDLE AGES

After them came that long dark vista of the earlier Middle Ages. Here and there in the ancient and medieval chronicles, amongst the "sad stories of the death of Kings," there are credible accounts of the last illnesses of the royal and the great, sufficient to provide the material for a diagnosis. Such descriptions, however, are too infrequent to be regarded as a fruitful source of information for our present purpose.

THE RENAISSANCE

Medical recording had to wait until 1507 for its renaissance. That year saw the publication of the posthumous masterpiece of the Florentine physician, Antonio Benivieni, *De abditis nonnullis ac mirandis morborum et sanatationum causis*. The discussions of the hidden causes drive from a study of 24 post-mortem examinations, and each individual finding is linked to a short description of the earlier clinical assessment of the patient.

In this simple form of correlation we can see the germ of the clinicopathological conference of today, and Benivieni as the precursor of the Cabots.

If royal mortality provided an indifferent field for research, there is, at any rate, one satisfactory piece of detailed medical history writing which leaves little unsaid about the health and habits of James I of England. The author was Theodore Turquet de Mayerne, a Swiss, who commenced practice in Paris, became physician-in-ordinary to the then King of France, Henry IV, and in 1611 was invited to England to take up the appointment of first physician to its monarch.

The memorandum "On the preservation of the King's health," a document of upwards of 4000 words, was written in December, 1623, two years before the King's death. It is as candid and thorough an appreciation of the psychology and pathology of a human being, albeit a King, as ever pen communicated to paper. For any historian of the troubles of the Stuart dynasty, this portrait is of ætiological significance, but, in this context, only a few of its passages need be quoted from Sir Norman Moore's translation. It commences thus:

> James the First, King of Great Britain, was born at Edinburgh in the year 1566, on June 19th, at half-past eleven in the morning, and is now aged over 57 years. He had a drunken wet-nurse and was suckled for about a year. He has a very steadfast brain, which was never disturbed by the sea, by drinking wine, or by driving in a coach.
>
> He is easily affected by cold and suffers in cold and damp weather. His chest is broad and well formed, and the vital parts contained therein have strong and lively warmth and never are afflicted unless as a result of morbid conditions elsewhere. The liver naturally good, large, of much blood, warm, liable to obstructions, and inclined to generate much bile. The spleen now easily heaps up melancholic juice, the presence of which is indicated by various symptoms. There is no swelling in either of these viscera and no hardness. Each hypochondrium is soft and never distended, except with wind. The stomach is always ready for the burden of a large quantity of food and is prompt to get rid of any hurtful excess, chiefly by the bowel.
>
> His legs seem not strong enough to sustain the weight of the body. His habit loose and of pervious texture, and he readily heats with dry heat. Skin thin and delicate, so that it itches easily. Fauces narrow, causing difficulty in swallowing, which defect is hereditary from his mother and grandfather James V of Scotland.
>
> *Air.*—His Majesty bears all changes of air fairly well; in damp weather with a south wind he is attacked by catarrh.
>
> *Food.*—As regards food he does not much amiss except that he eats no bread. He generally takes roast meats. Owing to want of teeth he does not chew his food but bolts it. Fruit he eats at all hours of day and night.
>
> *Drink.*—In drinks he errs as to quality, quantity, frequency, time, and order. He promiscuously drinks beer, ale, Spanish wine, sweet French wine, white wine (his normal drink), and Muscatelle wine (whence he has diarrhœa), and sometimes Alicant wine. Nevertheless, he does not mind whether wine be strong or no so it be sweet. He has the strongest antipathy to water and all watery drinks.
>
> *Affections of the mind.*—His mind is easily moved suddenly. He is very wrothful, but the fit soon passes off. Sometimes he is melancholy from the spleen in the left hypochondrium exciting disorders.
>
> *Excreta.*—He often blows his nose, sneezes very often. Does not spit much unless from catarrh. Stomach easily made sick if he retains undigested food or bile. Vomits with great effort, so that after being sick his face appears for a day or two spotted with red spots. Much wind. Vapours from his stomach precede illness. The alvine discharge is uncertain and depends on the nature of his food, which often produces morbid changes. A tendency to looseness gets rid of a burden produced by what he has eaten.
>
> *Former illnesses and present aptitude to various morbid dispositions.*—The King to the sixth year of his age was not able to walk, but was carried about, so weak was he from the bad milk of his drunken nurse. Between the second and fifth year he had smallpox and measles. In his fifth year for twenty-four hours he had suppression of urine, nevertheless no sand or slime was ejected.
>
> He is of extreme sensitiveness, most impatient of pains: and while they torture him with most violent movements his mind is tossed, and bile flows around his præcordia, whence the evil is not relieved, but made worse.
>
> He demands relief and freedom from pain, little considering about the causes of his illness.
>
> *As to remedies.*—The King laughs at medicine, and holds it so cheap that he declares physicians to be of very little use and hardly necessary. He asserts the art of medicine to be supported by mere conjectures, and useless because uncertain.

Mayerne, with his uncanny observation and assiduous *curatio*—he proposed a placebo for every trivial symptom—nevertheless paid tribute to ancient and medieval doctrines. For him catarrh descends from the brain to produce coryza, the humours boil in the stomach, and the spleen from its seat in the left hypochondrium excites disorders. More than seven years before Mayerne completed his memorandum, William Harvey had already proclaimed the circulation of the blood. And with its ultimate general acceptance physiology shook off the strings of Galen, and medicine began, however tentatively, to take its modern shape.

The experimental method established itself; logical reasoning replaced speculative opinion; cause and effect began to be bracketed together in the minds of the medical faculty.

MORGAGNI

Let us skip another century and take counsel of Giovanni Battista Morgagni, chief professor of anatomy at Padua and president of the university. He obtained his first appointment in Padua in 1712, and there remained for over fifty years, amassing reputation and honours as anatomist, pathologist, physician, man of affairs, and philosopher. He died in his ninetieth year in 1771, ten years after the publication of his monument, "more durable than brass," the great repository of medical and pathological experience entitled *De sedibus et causis*

TUBERCULOSIS IN GLASGOW

SIR,—I am sorry that in my letter of May 2 I stated there was no consultant in tuberculosis in the Western Region This is inaccurate, as pointed out by several of your correspondents I was thinking, when writing, of the clinic service and did not intend my statement to be inclusive of medical superintendents of sanatoria or orthopædic surgeons doing mainly tuberculosis Despite this, it is true that this Western Region is the most poorly staffed in the United Kingdom, although the problem is most acute here A statement from the Regional Board on the staffing of the chest clinics and associated beds would be most instructive to your readers The medical staff in these clinics has been pressing for improvement for many months The death-rate, as elsewhere, has shown a welcome fall The number of notifications of new cases and of children developing tuberculous meningitis leaves no room for complacency

The vituperative letter of the Medical Officer of Health obviously reflects his sense of frustration in the face of the hopeless housing situation This is understandable, for at present building rates it will take between forty and fifty years to supply the needed 150,000 houses This is the figure shown in 1945 to be essential to relieve overcrowding and to replace unfit and insanitary houses A prominent member of the housing committee stated in a public meeting recently that there were 161,000 families waiting to be rehoused These facts will enable your readers to appreciate the bare outline of the problem The instance I gave revealed just a little of the human misery hidden by such figures

Tuberculosis in Glasgow will not be eradicated until a fully staffed medical and nursing service is associated with a radical approach to rehousing The Regional Board and the Corporation of Glasgow are challenged by a situation unparalleled in the British Isles, and all resources should be mobilised to give them much-needed help

Central Middlesex Hospital,
London N W 10

HORACE JOULES

SIR,—By drawing attention in your columns to the deplorable position with respect to tuberculosis in the city of Glasgow, Dr Joules has done his Scottish colleagues a valuable service, and the substance of his comments is certainly accepted by the overwhelming majority of general practitioners in the area

One can only deplore that the Medical Officer of Health and the Senior Tuberculosis Officer consider it "impertinent for someone from the South of England to make comments on the situation" The tone and content of their reply confirms the strong suspicion existing in Glasgow that those concerned with the tuberculosis service are guilty of complacency, one instance of which is their quotation of improved mortality rates While such improvement is, of course, to be welcomed, it means nothing more than that more patients with tuberculosis are being cured, or are being kept alive longer, as a result of the surgical and chemotherapeutic innovations of the past decade But it does *not* mean that the tuberculosis endemic is under control, nor does it means that the rate of new notifications is falling *On the contrary* the following statistics for new notifications of pulmonary tuberculosis in Glasgow tell their own grim story

Year	*Cases*
1935	1757
1940	1908
1945	2641
1950	2446
1951	2207
1952	2235 (provisional)

If the 1952 figure is broken into the quarterly notifications there is a clear indication of a substantial deterioration, which has been accelerated in the first quarter of 1953

	1951	*1952*	*1953 (provisional)*
3rd quarter	514	519	—
4th quarter	496	564	—
1st quarter	—	547	622

Why does not the M O H, whose job I have always understood to be the prevention of disease, not quote these figures instead of the number of deaths ?

Is it not evidence of complacency when the Western Regional Hospital Board announces, as it recently did, that *after 3 years' consideration* work was now to begin on new chest clinics and advertisements were to be placed for new consultant posts ? Is this the realistic sense of urgency possessed by the board ? Dr Laidlaw and Dr Gemmill tell us how many tuberculosis consultants there are in Glasgow Perhaps they will now tell us how many, if any, are at work outside of hospitals, in the chest clinics

The Western Regional Board area has the lowest number of hospital beds, per annual new cases or per population, of any of the regions of Scotland, excepting the South-Eastern Yet nearly two-thirds of the new notifications in Scotland each year are in the Western Region Does not this suggest complacency ?

Dr Laidlaw and Dr Gemmill adduce historical reasons for Glasgow's specially bad housing record Instead of defending the status quo in housing, they should be using their influence to demand a special allocation to meet the city's crying need, as shown by the following comparison of percentages of population in 1951 living at a density of over 3 per room and of 2–3 per room

	Over 3 per room	*2–3 per room*
England and Wales	0 3	1 8
Glasgow	8 6	17 3

There are very nearly as many people living at more than 3 to a room in the Glasgow region alone as in the whole of England and Wales

Before throwing stones at Dr Joules, let Dr Laidlaw and Dr Gemmill put their own house in order When the Glasgow tuberculosis physicians and administrators achieve a speed of admission of new cases to hospital comparable to that in the area around Dr Joules's hospital, we will perhaps allow them their complacency

Glasgow

R LESTER BLACK

PNEUMONIA COMPLICATING CHICKENPOX

SIR,—In connection with your annotation of April 11, I should like to describe the following case

A woman, aged 21, was admitted to this hospital on Sept 28, 1952, with a diagnosis of chickenpox There was a typical, fairly profuse rash of characteristic distribution and appearance Temp 102°F, pulse rate 100 per min, respirations 22 per min Examination of the chest showed no definite physical signs, but the patient appeared slightly cyanosed

Routine treatment was started—namely, local application of dusting powder and oral hygiene Because it was judged that the rash, when fully developed, would be profuse penicillin was ordered, 250,000 units six hourly, in order to keep the rash "clean"

On Sept 29 the temperature was still high—103°F—and the patient had a slight cough, otherwise she was not complaining Over the left lower chest the percussion note was dull, and there were generalised fine crepitations in the lower half of the chest on both sides The respiration rate was still 22 per min

On Sept 30 the patient's cough was slightly troublesome and productive Radiography showed "gross mottling throughout the lung fields, which in the presence of a normal heart and obvious absence of industrial occupation is suggestive of Boeck's sarcoid or more probably a miliary type of pneumonia" Examination of the sputum showed no departure from the normal bacterial flora A blood count showed 11,000 white cells per c mm with no unusual differential count *morborum*. In that great work, clinical histories march side by side with the revelations of the post-mortem table, and wherever possible a correlation is established between them. "The Seats and Causes" is in construction a collection of 70 letters, each dealing with a separate subject or disorder. It runs to about a million and a half of words, mentions many hundreds of individual patients both "intra-vitam" and "post-mortem," and rejoices the heart of the reader by the provision of four comprehensive and associated indexes.

In the introduction Morgagni modestly introduces both himself and the original recipient of the letters:

> I have not dwelt long upon explications, and have taken care to intersperse other remarks relative to the practice of medicine, some of which relate to the history thereof, and some to the history of anatomy, and finally, many things which relate to the pursuits and studies of the young gentleman to whom I addressed the letters, and this with an intention to withdraw his imagination for a while, from the horrid and perpetual idea of diseases and dead bodies.

There is a Chaucerian flavour about the citizens of Morgagni's world. Little phrases etch and identify them. Here are some of the patients:

> A nobleman of Bologna; a woman of 40 years of age of a fleshy habit but a sallow colour, having eaten onions; an ostler, near sixty years of age, tall and fat, being used to eat much and drink very freely; a woman of Padua, by name Jacoba, the wife of Angelo Zanardi—finding 13 ribs on each side of her; a monk who was noble both in his birth and his manners; a woman of 75 years of age, of a manly aspect and very fat; a certain man skilled in the art of music, and the use of its instruments.

The first of the 70 letters is inscribed "Of Pain in the head." It parades before us "A boy of 13 years of age, of a ready wit, whose brother and sister had died of a consumption" followed by "a man about 40 years of age, (who) had been liable for many years to a pain in the right hypochondrium." "To those two histories," continues Morgagni, "give me leave to add a third, which though it does not relate to a man but a sheep is far from being unworthy of our notice."

Where there is such a wealth of material it is difficult to select. From over 700 necropsies, here are three histories, neither better recorded nor more brilliantly depicted than scores of others. Each is in its way notable. The first is probably the original picture of the Stokes-Adams syndrome; similarly, the second is an early, if not the earliest record of a patient in the grip of "angina pectoris"; the third vividly recounts the rupture of an aortic aneurysm.

I

> "A merchant at Padua of 64 years of age, of a square stature, and of a fat habit of body, but not to excess. He having been formerly subject to a rheumatism . . . had been cured by medicinal remedies: so that notwithstanding he was taken up with many and various businesses continually, he was, nevertheless, in good health; when of a sudden he was seized with very violent affections of the mind. . . .
>
> "A few days, after these commotions, a kind of vertigo coming on, he fell down—and on the day following he began to be troubled with convulsive motions, together with an attack similar to epilepsy. . . ."
>
> After several months during which the patient improved and then relapsed, Morgagni's services as a physician were asked for. He writes: "whom visiting by way of consultation I found with such a rarity of the pulse that within the sixtieth part of an hour the pulsations were only 22—and this rarenes which was perpetual . . . was perceived to be even more considerable, as often as even two (epileptic) attacks were at hand—so that the physicians were never deceived, if from the increase of the rareness they foretold a paroxysm to be coming on."

II

> "The mother of a family, who was two and forty years of age—had long been subject to a kind of paroxysm, which appeared in the following manner: on using pretty quick exercise of body, a kind of violent uneasiness came on, within the upper part of the thorax on the left side, joined with a difficulty of breathing, and a stupor of the left arm, all which symptoms soon remitted when those motions ceased. This woman then, having set out . . . from Venice to go up the continent in a wheeled carriage, and being cheerful in her mind, behold the same paroxysm returned, . . . and saying that she should die, she actually died on the spot."
>
> At the post mortem Morgagni found "the Aorta—not a little dilated at the curvature" with "compleat bony scales," of a small size; not to mention frequent marks of ossification being begun."

III

> "A man who had been too much given to the exercise of tennis and the abuse of wine, was . . . seized with a pain of the right arm, and soon after of the left joined with a fever. After these there appeared a tumour on the upper part of the sternum like a large boil; by which appearance some vulgar surgeons being deceived, and either not having at all observed, or having neglected the pulsation, applied such things as are generally used to bring these tumours to suppuration, and these applications were of the most violent kind. As the tumour still increased others applied emollient medicines from which it seemed to them to be diminished. But it not only soon recovered its former magnitude but was . . . seen to increase every day.
>
> "Wherefore, when the patient came into the Hospital of Incurables . . . it was equal in size to a quince and . . . began to exude blood in one place so that the man himself was very near having broken through the skin . . . when he began to pull off the bandages, for the sake of showing his disorder.
>
> "But . . . he was prevented going on, and ordered to keep himself still, and to think seriously and piously of his departure from this mortal life, which was very near at hand and inevitable. And this really happened on the day following from the vast profusion of blood that had been foretold, though not so soon expected by the patient. Nevertheless, he had the presence of mind immediately as he felt the blood gushing forth, not only to commend himself to God, but to take up with his own hands a basin that lay at his bed-side, and, as if he had been receiving the blood of another person, put it beneath the gaping tumour."

THE CABOT CASE-RECORDS

Our panoramic sweep covers another century and a half and crosses an ocean to New England. There, in Boston, at the Massachusetts General Hospital, April, 1914, saw the commencement of an enterprise in the Morgagni mode and tradition—the Cabot Case Records.

The primary imaginative inspiration came from the brothers Cabot—Richard the physician and Hugh the surgeon. But week by week since their day the ante-mortem and post-mortem records of the hospital have been used to provide the dialectical and demonstration material for an inquisition, known throughout the world as the clinicopathological exercise or conference.

Approximately 5000 cases have been carried to a complete conclusion and elucidation at these conferences, and recorded accordingly. Only rarely has the arbiter, the pathologist, had to say *causa mortis ignota*. This M.G.H. collection is a thing unique in the modern medical world.

The original conferences were the private and somewhat informal arena of the Cabots and their students. Later, the circle of disputants was enlarged, and now each Thursday-morning conference has its own pair of prima donnas, sometimes from the resident company, sometimes guest artistes.

Comparisons between 1914, or even 1924, and the present day mark the tremendous increase in the armamentarium of diagnosis, a change in the types of disease encountered, and the rising level of the age of patients.

Only on a few diseases can one reasonably contrast the showing of the old warriors and the new.

For those who delight in such comparison I would recommend a study of the differential diagnosis of miliary tuberculosis. They will find that, despite the greater refinement of X-ray technique and the evolution of laboratory procedures which have aggrandised the electrolytes, the mother wit and experience of the clinician

In view of the radiographic appearance and the fact that the chest condition had arisen in the acute stage, the patient was put on aureomycin 0 5 g six hourly

Within thirty six hours the temperature, pulse, and respiration were normal, and the patient made an uninterrupted complete recovery A further radiograph seven days after the first showed normal lung fields A specimen of blood taken on Oct 9 contained cold agglutinins 1 32, examination for M G streptococcal agglutinins was negative

Pneumonia during an attack of varicella is extremely uncommon [1,2] In the case described here, the patient's rapid improvement coinciding with the giving of aureomycin (she had previously had 1,500,000 units of penicillin) would suggest that this was a case of varicella complicated by virus pneumonia with secondary bacterial infection The fact that this pneumonia was present at the onset might suggest that it was due to the varicella virus That this virus does cause pneumonia has been shown by the finding of varicelliform lesions and characteristic bodies in the lungs post mortem

Infectious Diseases Hospital
Milton Road, Portsmouth
IAN M McLACHLAN

HOSPITAL COSTING

SIR,—Dr Avery Jones's contention (May 16) that a general community hospital should have at least 90% bed occupancy, and that 93% bed-occupancy is perfectly feasible, should not pass unchallenged To allege that lower bed-occupancy figures are a "large scale extravagance" is an extraordinary statement from a clinician of Dr Avery Jones's standing and experience

Members of lay committees find it extremely difficult to appreciate the significance of percentage bed-occupancy figures and they are unlikely to be helped if doctors themselves do not understand them I would submit that *high* percentage occupancy figures may reflect an inflexible system of bed-allocation and may be a source of extravagance I would, however, first of all plead that we beware of paying too much attention to all these figures There are several points which need emphasis

1 Percentage bed occupancy approaches 100 in institutions for the chronic sick, and high figures are achieved in all hospitals or wards which have a waiting list and a slow turnover of long-stay cases

2 The monthly turnover of cases in a ward or hospital may be greatly increased without altering the percentage bed-occupancy—in fact, the latter almost invariably falls The quicker the turnover the more likely it is that beds will fall vacant unexpectedly, and the more difficult it is to fill them promptly

3 An increased turnover, despite the almost inevitable fall in percentage bed occupancy means greatly increased work for the medical and especially the nursing staff

4 Only those on the spot who have clinical responsibility for the patients can decide how best to use the available resources, and it is doubtful whether any figures, however detailed, can reflect the remarkable variations between one ward and another

5 It is usually unjustifiable to compare percentage occupancy figures for different hospitals

6 It is sometimes of value to compare the percentage bed occupancy figures for the same hospital at different times, *but only in conjunction with other essential data* However, only the grossest variations are likely to be of much significance, and considerable circumspection is necessary in their interpretation.

There has, of late, been an unhealthy preoccupation with "phoney" statistics of all kinds, and this has been encouraged by the ever-increasing flood of monthly and other returns demanded by the Ministry and the regional hospital boards Associated with this trend one has at times noted a regrettable lack of honesty and care in compiling these returns Nevertheless, however honest and careful we all are it is very doubtful whether the compilation of such figures is of any real value outside the hospital itself I entirely agree with Dr Avery Jones that a report on this subject by an independent medical foundation would be most opportune, and fortunately such a report is to be published by the Administrative Staff College of King Edward's Fund

It may be relevant to recall that at one large hospital at which I once worked my ward sisters regularly asked me to keep patients in at the end of each month "so that the bed returns don't look too bad" I ignored their pleas and pointed out that, although this might be to the detriment of their bed returns, it was to the advantage of the patients, the nursing staff, and the hospital finances Unoccupied hospital beds are surely less of an extravagance than unnecessarily occupied ones or ones kept deliberately filled by clinicians and administrators who are keen to make a good "score" in their bed returns

Real statistics can be of real value, but "phoney" figures are fallacious and mere humbug Fortunately most patients want to get out of hospital as soon as possible, and most doctors are only too anxious to maintain a rapid (sometimes too rapid) turnover The integrity of the individual doctor in the service of his patients is surely the only real safeguard against wastage of hospital beds All the figures in the world and all the Ministerial injunctions will never achieve so much as a contented hospital staff who are left to do their best for the community they serve

I am certain that the efficiency which Dr Avery Jones seeks is more likely to be achieved if the hospitals gain greater financial and administrative independence rather than by comparing figures in the annual reports of the Ministry of Health

Radlett Hertfordshire
R S MURLEY

"HARLEQUIN" COLOUR CHANGE IN THE NEWBORN

SIR,—I read with interest the account of this condition by Dr Neligan and Dr Strang,[1] and would like to describe an example of it

Early in September, 1952, a 24 hour-old twin girl was noticed by the nursing staff to exhibit colour changes in the skin—"half of the body became a deeper red, may be left or right side" At 48 hours these changes in skin colour were striking The infant, lying on its back, showed on its right side a brilliant red with a sharp line of demarcation down the centre of the face and trunk The pupils were equal, and to the touch there was no obvious difference in skin temperature After a few minutes the left side began to flush and the right side slowly faded. For the next week these changes occurred up to 11 or 12 times daily, sometimes involving one side of the body and sometimes the other, and lasting 3–4 minutes on each side

At that time inquiry locally revealed no previous experience of this phenomenon. This infant, the first of twins in a primipara, had a birth weight of 5 lb $3^1/_2$ oz There had been a transverse arrest of the head, necessitating extraction with Kielland forceps, the head crowned in the left occipito-anterior position. It was thought that perhaps there had been some trauma to the sympathetic chain as a result of a difficult rotation However, the second child, also a girl, with a birth weight of 4 lb $13^1/_2$ oz, had been delivered easily but at 36 hours exhibited similar colour changes The attacks were not so pronounced and were less frequent They ceased on the 5th day Attempts to photograph these changes were unsuccessful

Following this the nursing staff kept a closer watch on all babies having incubator care, and further examples were observed.

Our observations are essentially similar to those described by Neligan and Strang in that if the infant is lying on its side the lowermost half of the body is the brighter red, changing the position of the infant will reverse these changes If left undisturbed the changes

are often the deciding factors. And over the years the personal honours are evenly divided.

THE ESSENTIALS

It is time to gather together the lessons of our circumspection in time and place. Nearly 5000 years come within our compass, for the earliest Egyptian record precedes the Edwin Smith papyrus by a millennium. From their primitive salves, linen rolls, and incantations to our antibiotics and radioactive isotopes is a gigantic stride. Yet we still use salves and bandages, we still place men at their mooring stakes. Now as always observation and experience are the foundation upon which diagnosis, treatment, and prognosis are built. Individual men and women are no less prone to error, and that fallibility is another of the companionable common factors which help to bridge the ages.

From the point of view of the student of records, those treasures which he rescues from the archives can never be better than the best of the efforts of the best of the contemporary clinicians and scientists.

One does not expect Mayerne to anticipate and outdo Morgagni. The trouble arises when the physician of the day falls short of the Hippocratic standards, and uses the cant phrases of the moment instead of his mother wits.

Let us see if we can distinguish some of the essentials of good record-keeping as we have already observed them.

Above all comes the scheduling of the facts, and the little verse of Kipling mentions most of them.

> " I keep six honest serving-men, (they taught me all I knew)
> Their names are What and Why and When, and How and Where and Who."

But in our studies we have been given more than facts. The best records have been pictures, and the attributes of those pictures have been these—at least as I see them.

Order has been a characteristic throughout. What more orderly than the presentation of that Egyptian warrior's broken nose, or the recital of the pathology of the living as seen in James I.

Accuracy.—Here we have no yardsticks except we regard as such our ability, despite the efflux of time, and the difficulties of definitions and translations, to recognise the descriptions and the diagnoses as comparable to something within our knowledge and experience.

Brevity.—Except Mayerne, the writers of all our texts are masters of concise expression. Morgagni is discursive at times, but that is when he is bent on instructing his young friend. When he wills it, no-one can epitomise more pertinently or more epigrammatically. Then other less important virtues have been disclosed—*Balance* in the presentation of a mass of information; and *Saliency*, the gift of emphasising the outstanding features.

Finally, we come to *Selectivity*. Except for Mayerne—and his essay was on a special theme—all our teachers have been selective in the information they have laid before us. They have not invited us to study everything, but only certain examples from their several collections.

Hippocrates, in writing the Constitutions, obviously draws upon more clinical material than he leaves with us in the individual cases of the books of *Epidemics*. Morgagni, also, tells us that, if he were to write all that he knows about aneurysms, it would fill a volume in itself.

It seems impossible to contemplate the holding of a grand clinicopathological conference on every inguinal hernia or tonsillectomy. The essential facts must be recorded. The six honest serving-men must make their mark.

Thereafter, as with our predecessors, a wise discretion will determine what shall be set out in detail, and what omitted, for the guidance, instruction, and charitable consideration of posterity.

THE HEALTH OF A TROPICAL PEOPLE

A Survey in Ceylon

H. CULLUMBINE
M.D., M.Sc. Sheff.

LATE PROFESSOR OF PHYSIOLOGY AND PHARMACOLOGY,
UNIVERSITY OF CEYLON, COLOMBO

II. ENVIRONMENT, HEALTH, AND PHYSIQUE

THE difference in the incidence of infective and parasitic diseases in tropical and in temperate countries is well known, but owing to incomplete and inaccurate registration of deaths precise comparisons are difficult. Ceylon has probably the most comprehensive system of registration in all Asia, and the mortality figures can be compared with those of Western countries. Such a comparison has been made between Eire and Ceylon, which resemble each other in that they are of much the same size, have predominantly agricultural economies, and have only one large city.

Since 1946 the crude death-rate in Ceylon has dropped suddenly to about the same level as in Western countries. This can be attributed to the near eradication of malaria by the use of D.D.T. as a control measure for mosquitoes. The fall in the incidence of malaria has been accompanied by a big reduction in infant mortality, maternal mortality, and in some of the other major causes of death (table I).

TABLE I—DECREASE IN DEATHS BETWEEN 1946 AND 1949

Cause	Decrease	
	No. of deaths	% of total decrease
All causes	44,018	100
Malaria and pyrexia ..	16,459	37·4
Pneumonia	3193	7·2
Influenza	588	1·3
Infant deaths	10,755	24·4
Puerperal deaths	2081	4·7
Dysentery	1116	2·5
Diarrhœa and enteritis ..	1913	4·3

Some of these reductions can be attributed to the destruction by D.D.T. of vectors of disease other than the mosquito, but not all can be so explained. It could be claimed that the lowering of the malaria morbidity has increased the general resistance of the population. We might then have expected an interval between malaria eradication and the evidence of increased resistance to other diseases, but all the mortality reductions occurred together and suddenly.

In one year the general death-rate fell from a level typical of Asian or backward countries to one comparable to that of the more prosperous and advanced countries. At the same time the mortality pattern has changed. Although 1 in every 9 deaths is still due to parasitic and infective diseases and only 1 in 14 to renal-cardiovascular diseases, there are definite signs that the mortality picture is becoming "Westernised." The proportion of deaths due to diseases of the middle and later years of life is gradually rising and that due to infective diseases is falling. The relative rapidity of

last up to 25 minutes In 1 case the changes included the tongue No pupillary changes were noted The attacks appear to have no pathological significance, as infants seen to be affected have thrived

These observations have so far been confined to infants in incubators This includes all premature infants and those in whom perhaps there has been some difficulty in establishing respiration The remainder of the babies born in this 100-bed maternity unit are dressed and placed in ordinary nurseries, where such changes would not be so easily observed So far the highest birth weight among infants in whom such changes have been observed was 7 lb 6 oz The attacks may start from the *1st day of life and up to 71 attacks in one child* have been seen Attacks seem to be commonest soon after feeding In one premature infant with a birth weight of 2 lb 12½ oz no attacks were observed until the 21st day, at which time the weight was 3 lb 6½ oz

It was the impression of those who witnessed these *attacks initially that* one side actually "flushed" indeed the staff referred to "blushing babies" We are still not convinced that there is pallor of one side as opposed to flushing of the other, and in only 1 case did we feel that one side became paler than normal One infant who showed colour changes was cyanosed This infant had been delivered normally at full term (birth weight 7 lb 6 oz) On the same day the nurse's notes recorded "sudden colour change, blue on left side, right side quite pink, duration 2–3 minutes"

After six months in a unit in which 133 babies have been nursed, these changes have been observed in 9 cases We have no better explanation than that put forward by Neligan and Strang

MYSOLINE IN THE TREATMENT OF EPILEPSY

SIR,—Dr Butter, in his article of May 23, makes his report on sane male patients Since 'Mysoline' became available last year it has been used at Long Grove Hospital for some of the patients in the wards containing mostly epileptics In addition to their epilepsy all the patients have some mental disorder

Disregarding the effect on the frequency of convulsions, which has always been equal to, and in many cases better than, that of phenytoin and phenobarbitone, the change in patients' behaviour is of special interest Some patients improved dramatically in behaviour and sociability They showed more readiness to accept treatment and to cooperate in ward routine These were recognised as cases in which the mental disorder was more one of affect than of personality Among these was a case with psychomotor attacks in which, as in Dr Butter's case of the same kind, great improvement was seen

A larger number of patients derived little appreciable benefit, and it has become clear that the more psychotic the patient's thoughts and behaviour the less benefit he is likely to obtain from this drug Such symptoms are frequently false beliefs of persecution or other ideas of reference, and these appear to mask any change of mood, so deeply are they rooted in the patient's mind Patients with obvious mental deficiency also appear to show little social improvement with mysoline

A report on mysoline in mental disorders was given at the meeting of the Royal Medico Psychological Association at Warley Hospital, Brentwood, Essex, on April 21, 1953, and the views expressed there are borne out by our experience at Long Grove Hospital

DAVID J ADDERLEY
ALAN B MONRO

KWASHIORKOR

SIR,—Kahn[1] has good cause to complain of the arbitrary and unpractical definition of kwashiorkor by Brock and Audret[2] in their W H O publication

The Ga, reported by Williams[3] to use the word, came to the Gold Coast as refugees from the slaughter at Benin by the Eyo or Yoruba at the end of the 16th century They borrowed religion, customs, and many words from their Akan neighbours[4, 5] *Kwashiorkor* is an Akan word

To compress 2500 years of Akan history into a paragraph has proved as difficult as getting the dormouse into the teapot[6–10] Behind the religions, Egyptian, Sabean, Libyan, and Numidian, with which the Akan have been in contact during this long period, lies the ancient philosophy of Babylon In this struggle between Good and Evil, misfortune to the individual that could not be accounted as the inevitable sequence of transgression of the Law was attributed to the Devil, his minions the Influences, or his friends and followers the Sorcerers

Nathaniel Uring,[11] on the Gold Coast in 1710, noted "The Natives have no Knowledge of Letters, but have a Notion of God which they call John Company (*Onyankopon*), they say he is a good Being, and hurts no Man, and therefore pay Adoration to the Devil (who they call Bone Sam (*Sasabonsam*)) to pacify him that he may do them no Harm" Rattray[12, 13] describes Sasabonsam as red in colour, and the wizards and witches as having red auræ All are very greedy

Sir A B Ellis[14] pointed out that the Akan (Gold Coast) Ewe (Dahomey), and Yoruba (Nigeria) all came from the interior, and had much in common in religion, customs, and language He did not see *Kwashiorkor* on the Gold Coast, but described *Abiku* (destined for death) the Demons who seized the bodies of Yoruba children up to the age of 12 He is quoted by Sir J G Frazer[15] "On the Slave Coast when a mother sees her child gradually wasting away, she concludes that a demon has entered into her child and takes her measures accordingly To lure the demon out of the body of her offspring she offers a sacrifice of food, and while the devil is bolting it, she attaches iron rings and small bells to her child's ankles, and hangs iron chains round his neck The jangling of the iron and the tinkling of the bells are supposed to prevent the demon, when he has concluded his repast, from entering again into the body of the little sufferer" The late Marshall Findlay and I exhibited a collection of these anklets and bells among other phylacteries in 1951[16]

In the traditional customs of marriage in Britain the bride puts on something old and something new, something borrowed, and something blue,' and this is stated vaguely to be for luck The old and the new are proved defences against the Devil[17], the borrowed is a disguise[18], and the blue is the antithesis of red, the Devil's own colour The bauchles tied to the back of the carriage are a further prophylactic use of the old The ringing of the church bells, and the music and noisy merriment that follow, are the driving off of the Devil by noise[18] The wedding feast is an appeasement of any possible ill wishers These indeed are precautions against *Kwashiorkor*, the Gudeman, or his friends, interfering with the fruits of matrimony, the children

As Kahn has pointed out, malnutrition due to pap feeding has been and still is world-wide That is to say, pap has been, and still is, considered, by some, an adequate substitute for mothers' milk It is homœo avoided, complete recovery takes place in three to twelve months. Doxiadis has shown that the prognosis is good when the condition is satisfactorily treated from a fairly early stage, but that otherwise permanent renal damage is likely. The relation of the disease to nephrocalcinosis of adults remains uncertain.

Recently Lightwood and Payne[20] described a group of infants with the same gross clinical features as those of idiopathic renal acidosis—anorexia, vomiting, constipation, and loss of weight—but in whom there was no acidosis and the urine was normally acid. There was, however, hypercalcæmia with a blood-calcium level of 12–15 mg. per 100 ml., and the blood-urea and plasma-protein levels were also raised. After an illness lasting from five to fifteen months or more, slow spontaneous recovery took place. Lightwood and Payne described 10 cases of this syndrome which they called "idiopathic hypercalcæmia of infants." The cause is unknown.

Action of Parathyroid Hormone

Primary disturbance of the function of the parathyroid glands is rare. The symptoms of hyperparathyroidism are so varied that the condition may long remain unrecognised; it may be diagnosed only after renal stones have been removed, or after bone thought to be involved by tumour has been resected and been found to be affected by osteitis fibrosa. Murphy et al.[21] remark that the manifestations of hyperparathyroidism include, as well as bone deformities and loss of stature, weakness, fatiguability, mental changes, weight loss, bone and muscle pains, gastro-intestinal symptoms, polydipsia, and renal colic. Hypoparathyroidism is hardly less versatile in its manifestations,[22] which range from tetany, paræsthesiæ, cramps, and laryngeal stridor to gastro-intestinal disturbances, mental derangement or retardation, cataracts, ectodermal lesions, and poor dentition.

Collip,[23] who first prepared parathyroid hormone (P.T.H.), showed that his extract could raise the serum-calcium level in normal and parathyroidectomised dogs, but it was not clear whether this was secondary to a primary action on the bones or on the kidneys. The main exponents of the bone theory [24–26] suggest that P.T.H. stimulates osteoclastic resorption of bone with consequent reparative activity by osteoblasts, and that the changes in blood and urine levels of calcium and phosphorus are natural sequelæ of this primary action on bone. There can be little doubt that P.T.H. does affect bone directly, as Barnicot[27] showed in rats by parathyroid intracerebral grafts; bone was eroded only in close proximity to the parathyroid tissue. Ingalls et al.[28] also found histological evidence of osteoclastic resorption in nephrectomised animals treated with parathyroid extract. Moreover the time relations of the bone changes after administration of P.T.H. fit quite well with the observed changes in blood and urine levels of calcium and phosphorus.[26] The bone theory has, however, one obvious weakness; for, since both calcium and phosphorus are resorbed, hyperphosphatæmia as well as hypercalcæmia would be expected, whereas in fact hypophosphatæmia develops in uncomplicated hyperparathyroidism.

Albright[29] is the main advocate of the kidney theory of the primary action of P.T.H. He believes in the following sequence of events: (1) increased renal excretion of phosphorus; (2) lowered serum-phosphorus; (3) resorption of calcium and phosphorus from bone owing to a decrease in the saturation of the body-fluids with calcium and phosphorus; (4) increase in serum-calcium; (5) increase in urinary calcium; (6) further resorption of bone unless dietary calcium is adequately increased; (7) weak bones; (8) osteoblast stimulation, and therefore increase in both resorption and formation of bone. In this theory the basic assumption is the original renal tubular incompetence to reabsorb phosphorus; and Albright cites the observation that after an injection of P.T.H. the increase in urinary phosphorus precedes that of urinary calcium. Milne[30] exposed a fallacy in this reasoning when he administered calcium and phosphate separately but simultaneously into opposite arm veins, or gave preformed colloidal calcium phosphate; in each case the time relations in the excretion of phosphorus and calcium were the same as after injection of P.T.H. Milne has also pointed out that the increased urinary loss of phosphorus after administration of P.T.H. is insufficient to account for the observed lowering of the serum-phosphorus; for this is in dynamic equilibrium with the much larger phosphorus content of the extracellular fluid.[31] Thus there is still doubt as to the distribution of the phosphorus that disappears from the blood. Tweedy and Campbell[32] have provided clues by their radiophosphorus studies, in which they showed that the accumulation of labelled phosphorus reached values 20% higher in the liver and 18·5% higher in the kidneys in rats receiving parathyroid extract than in controls. Whether or not this effect is primary, Tweedy and Campbell established that P.T.H. increases the phosphorus clearance by the kidney. This has been confirmed by Milne,[10] who pointed out that the low phosphorus clearance in hypoparathyroidism is much more dramatically increased by P.T.H. than the relatively high phosphorus clearance of normals. Some of the clinical effects of hyperparathyroidism appear, on the other hand, to be caused chiefly by the direct effect of P.T.H. on bone resorption. Stewart and Bowen[33] have reported further data on the relative importance of the renal and osseous actions of P.T.H. They showed that in nephrectomised dogs intravenous administration of parathyroid extract immediately after operation produced within 8 hours the normal response of hypercalcæmia. They also developed the ingenious oxalate-tolerance test of parathyroid function, described earlier by Patt and Luckhardt.[34] In normal dogs intravenous administration of sodium oxalate

produced a precipitous drop in the serum-calcium, followed by a gradual return toward normal levels within 6 hours, but when the animals had *previously* had the thyroid and parathyroid glands removed there was no appreciable return of the serum-calcium towards pre-injection levels The recovery phase of the oxalate-tolerance curve in nephrectomised dogs was, however, found to be the same as that in normal animals, so **Stewart** and **Bowen** concluded that *the parathyroid gland exerts a control over serum-calcium that is primarily independent of the kidneys* Much other evidence [35] suggests, however, that the ability of P T H to raise the serum-calcium is greatly impaired in the absence of the kidneys, although the animal is then usually *in a far from physiological state*

Dent [36] has recently driven further nails into the coffin of the Albright theory as the sole explanation of parathyroid action He confirmed that in normal men any phosphorus diuresis after injections of P T H was only slight, and he found *that the serum-calcium* rose, whereas the serum-phosphorus tended to fall only if it was originally high (as it was in the hypoparathyroid cases studied by **Albright**) Artificial lowering of the serum-phosphorus did not lead to a rise in serum-calcium to maintain the solubility product, and hyperparathyroidism with renal failure and raised serum-phosphorus may be followed by the typical bone changes of von Recklinghausen's disease If **Albright**'s suggested sequence of changes were correct, one would expect osteomalacia and not osteitis fibrosa to result Very recently **Stewart** and **Bowen** [37] have shown that preparations of P T H inactivated by formaldehyde with respect to their power to raise the serum-calcium still increase the urinary phosphorus output in dogs That this phosphorus diuresis is an artefact is suggested by the similar results when extracts of spleen and thymus are administered **Dent** [36] has further drawn attention to the apparently irrational dissociation of the bone changes in hyperparathyroidism from the changes in the blood-electrolyte levels, and has suggested (as did **L'Heureux** et al [38] on the basis of electrophoretic studies) that there may be more than one parathyroid hormone, and these may differ in the locus of their actions

It seems clear that parathyroid extracts can act directly on bone and on kidney, and perhaps too much attention has been focused on which of these actions is primary, for the work of **Martin** and **Perkins** [39] suggests that P T H may have a quite different primary action **Martin** [40] has obtained data which seem to show that in some cases of hyperparathyroidism the calcium binding power of the serum-albumin is more significantly and consistently increased than in other cases which in turn significantly exceed normal values After surgical treatment of the hyperparathyroidism the calcium binding power of the serum-albumin usually returns to normal in cases without demonstrable persisting renal damage Perhaps such changes in the calcium-binding power of the body-proteins may explain the metabolic actions of P T H

THE COURT EXPERT

If two doctors were to disagree *about a diagnosis,* it would be patently absurd to call in a layman to settle the issue between them Yet, as we suggested a year or two ago,[1] something hardly less peculiar happens in *legal proceedings* whenever irreconcilable opinions are expressed by *medical experts* engaged by the opposing sides Sometimes, it is true, both parties may accept a written report prepared by a member of the medical profession, but in many important trials whose outcome largely depends on scientific evidence, there is a hiatus in specialist opinion which has to be bridged by judge and/or jury finding their own solution of a technical problem

Medicine being an applied science, it seldom deals *with facts* from which only one inference is possible Moreover, medical evidence can seldom be visibly and *conclusively demonstrated to the court* This is true not only where sanity *or mental disturbance* is in question, but *in almost every case where a medical* opinion involves forecasts or is the result of laboratory *investigation* which *goes beyond simple* observations Being unable *to verify* his statements, judge and jury *must rely on the intelligence and professional* conscientiousness of the expert witness Accordingly the *court has to concentrate on testing his impartiality* and *competence*

Much interest therefore attaches to an American experiment in which the Supreme Court of New York will appoint court experts other than those chosen by the contesting parties [2] For some time past, United States courts, in dealing with medical expert evidence have had difficulties similar to those encountered in Great Britain but perhaps even more sharply focused In the United States almost all the testifying is done by *a very small proportion of the doctors,* and the fees asked sometimes depend on the expert's rhetorical gifts as much as on his professional skill and eminence The preparation of experts' reports for each party, moreover, is one of the principal causes of delay in the disposal of cases where a personal injury has been sustained and where it is necessary to estimate future incapacity In these circumstances, the plan to be tried for a year in New York aims at "better and quicker justice" for *the solution of conflicting medical claims, by avoiding* the former system under which "*a plaintiff's* doctor may tend to describe his patient as just about killed while the defendant produces a doctor who hardly finds scratches" The leading professional State organisations, the New York Academy of Medicine and the New York County Medical Society, have agreed to appoint a panel of about sixty experts of the highest standing in the various branches of their profession, including orthopædics, neurosurgery, neurology, and psychiatry, on whose knowledge and aid the courts can call whenever the need arises If in the preparation of the trial it is found that the medical claims of the two parties differ widely, the judge will, on his own initiative, assign an expert from the panel to examine the plaintiff and to provide a written report which will be available both to the court and to the two parties This expert is not a referee such as we have in this country under the Workmen's Compensation Acts His report is not binding on the court, nor are the parties precluded from cross-examining the expert in person at the trial or from calling in other experts of their own choosing, though it is expected that the court expert's report will often be accepted by all concerned, since it offers from the outset high guarantee of impartiality and competence Finally, it is hoped that the new system will have "the

plasic, the child appears to like it, and when sick prefers it to milk. Not until the end of last century did the medical profession realise that it was inadequate. The pining and death of infants weaned on to pap were, therefore, in olden times, unaccountable—i.e., the work of the Devil. The fiend who stole the bodies and souls of children, mentioned by Sir Walter Scott,[19] was *Kwashiorkor*, a particular manifestation of the protean gentleman who was "going to and fro in the earth, and walking up and down in it."

The merits of *kwashiorkor* as a name for infantile malnutrition due to the protein deficiency of a pap diet are:

1. It indicates a widespread belief as to its ætiology which goes back to the Neolithic philosophers of pre-Adamic times.[20]
2. It is kenspeckle—i.e., outstanding and remarkable.
3. It is simple of pronunciation, and like Lawrence's *ruelli*, you can spell it almost anyway you choose, which cannot, I fear, be done with *Mehlnährschaden*, *hypothrepsia*, and other suggested descriptive alternatives reminiscent of the "Great text in Galatians."

Edinburgh, 3. A. MacPherson.

SPHAGNUM MOSS

Sir,—Your annotation (May 23) regarding the use of sphagnum moss for urinary incontinence recalls to my mind that prior to the first world war, when employed as a surgical dresser at a large provincial hospital, I had to see that the automatic pump, of the Sprengel type, draining the bladder in cases of suprapubic prostatectomy was working satisfactorily. Not infrequently they ceased to function (invariably owing to interference by the patient); so, to absorb the resulting overflow of urine, several muslin bags filled with sphagnum moss were packed round the patient. These kept him comparatively dry and comfortable; the bags swelled up in a most astonishing way to many times their original size.

ERYTHEMA MULTIFORME AND A.C.T.H.

Sir,—The exact ætiology of erythema multiforme still appears to be rather obscure. If the syndrome is caused by a single agent, it is probably due to a virus.[21] In support of this theory, keratoconjunctivitis was reproduced in rabbits' eyes from fluid taken from bullæ, and cytoplasmic inclusion bodies were demonstrated.[22] A virus has been sought in laboratory animals but without success. Steigman and Kelly,[23] reporting on a case treated with A.C.T.H., state that the ætiology of erythema multiforme may be multiple, sensitisation playing an important part.

On Sept. 15, 1952, a 9-year-old boy was admitted to hospital with erythema multiforme. There was a diffuse maculopapular rash covering the limbs, back, buttocks, and face. The lesions on the arms were surmounted by urticarial weals, several hæmorrhagic in character. A.C.T.H. was given, and there was a remarkable improvement within 48 hours, followed by a rapid recovery.

The rash developed whilst the child was on a hop-picking holiday. He became lethargic and feverish, and had conjunctivitis, chemosis, balanitis, and generalised pharyngeal injection. On Sept. 18 vesicular lesions appeared on the buccal mucosa, the chemosis increased, and photophobia developed. A chest radiograph showed no focal lesion. The highest white-cell count was 17,900 per c.mm., with only 2% eosinophils. A heavy growth of non-pathogenic hæmolytic streptococci was isolated from a throat swab. The urine was normal. The Mantoux reaction was negative to 1/100. The erythrocyte-sedimentation rate was 33 mm. in the first hour. On Sept. 21 A.C.T.H. was given (15 mg. six-hourly). Within forty-eight hours the rash and oral lesions had begun to subside. On Sept. 24 the dosage was reduced to 10 mg. six-hourly. Further bacteriological examination of the blood and urine was negative. On Sept. 30 A.C.T.H. was stopped. A follow-up in the outpatient department showed that he was quite fit and gaining weight, with no recurrence.

OPHTHALMIA NEONATORUM

Sir,—As you say in your leading article (May 16), gonococcal ophthalmia neonatorum, which was common towards the end of the last century, has now almost entirely disappeared. However, minor infections of the eyes in infants must still be one of the most common forms of neonatal infection, and the 1935 cases notified in 1950 must represent a very small proportion of those actually occurring. These infections seldom cause any permanent damage to the eyes, and it is surely high time that ophthalmia neonatorum ceased to be a notifiable disease.

I note that you recommend penicillin as by far the most effective form of treatment. I believe this to be untrue. In many maternity units a penicillin-resistant *Staphylococcus aureus* seems to be almost endemic, and in my experience about 80% of the cases of ophthalmia encountered are caused by this organism. Penicillin in these cases is of course useless. Sulphacetamide 30% or propamidine isethionate 0·1% drops are usually effective, and would appear to be the treatment of choice until the sensitivity of the infecting organism to various antibiotics has been determined.

TREATMENT OF ADVANCED MALIGNANT DISEASE

Sir,—Mr. W. G. MacGregor and Dr. C. L. Lewis (April 4) describe their experience with administration of A.C.T.H. and aureomycin in advanced neoplastic disease, as used by McGuire and McElhone.[1] About the time that method was introduced we had under scrutiny about fifty patients with inoperable neoplastic disease who happened to be on a similar schedule and had been maintained in comfort for a considerably longer time than we had believed possible with "orthodox" modes of cancer therapy. Against criticism of McGuire and McElhone's schedule[2] we could cite two reports[3 4] offering them indirect support. We doubt the correctness of their premise that "cancer" is a virus disease and hence amenable to antibiotic therapy, but we think that certain items in their schedule did have the effect of prolonging the comfortable life-span of their patients.

Two years ago, one of us reviewed the reasons why he gave an antibiotic-containing "animal protein factor" (A.P.F.) to patients with leukæmia and other cachectic diseases.[5] Not only was the expected anabolic effect forthcoming, but surprising hæmatological improvement as well. It now turns out that those patients who received A.P.F. were actually getting a combination of mycin antibiotic and a steroid, the latter having a pronounced eosinopenic action in laboratory animals. Furthermore, like McGuire and McElhone's, our patients were receiving plenty of milk and large doses of potassium. We used the milk to reduce intestinal proteolysis, and the potassium because in patients with severe adaptation

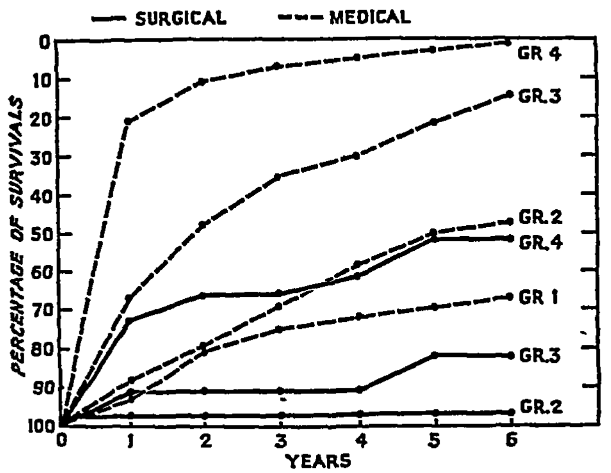

Fig 1—Survival rates in 30 cases of hypertension according to retinal grading

Present Series

At the Westminster Hospital we have, from the very first case, acted with a physician, and by far the greater number of the cases reported here were sent to us for operation by a medical colleague, who has borne the brunt of the work involved in following them up In every case we have also had the cooperation of the ophthalmic surgeon, the pathologist, and the biochemist

Bilateral lumbodorsal sympathectomy has been performed in 106 personal cases, 102 of which were done at the Westminster In addition there were 3 cases in which only one side was operated on in 2 of these death took place from cerebral hæmorrhage before the second stage, and in the 3rd (an experimental case over the age-limit) headache was relieved and the patient does not wish for, or in my opinion need, a second operation

Mortality

The Westminster patients have all been followed up The operative mortality was 5

(1) As already mentioned, 2 patients died of *cerebral hæmorrhage* in the second week after the first stage of the operation

(2) 2 other patients died of *local hæmorrhage* These were, on looking back, avoidable deaths In those days post operative hypotension was considered to be a common cause of death, but with the new drugs any dangerous fall of blood-pressure after operation can be counteracted. In our early cases we did not drain the wound, and at necropsy on these 2 patients a hæmatoma was found in the paravertebral space opened up by the operation A drain is now left in as a routine and a transfusion is given if a large loss occurs, but this has almost never been necessary, perhaps because of improved technique

(3) There was 1 case of *prolonged hypotension* following the use of the new methonium compounds as an anæsthetic

TABLE I—NUMERICAL VALUES OF CLINICAL FINDINGS (Smithwick 1951)

Factor	Numerical value
Cerebrovascular accident with or without minor residue	1
Abnormal electrocardiogram	1
Enlarged heart	1
Impending heart-failure	1
Phenolsulphonephthalein excretion less than 25% in 15 min. or less than 60% in 2 hr	1
Age 50 or more	1
Mild angina	1
Cerebrovascular accident with residue (cerebral deterioration or definite involvement of arm and/or leg)	2
Frank congestive heart-failure moderate angina	2
Phenolsulphonephthalein excretion less than 20% in 15 min.	2
Unsatisfactory response to sedation	2
Phenolsulphonephthalein excretion less than 15% in 15 min	3
Nitrogen retention	4

All our efforts to raise the blood-pressure failed No other cause of death was found post mortem

Classification

The cases have been graded according to the retinal changes, using the following classification

Grade 1—Mild narrowing or sclerosis

Grade 2—Moderate to marked sclerosis characterised by exaggeration of the arterial reflex and arteriovenous compression

Grade 3—Angiospastic retinitis characterised by œdema, cotton wool exudates, and hæmorrhages superimposed on a combination of spastic and sclerotic changes in the arteries

Grade 4—As for grade 3, but in addition measurable œdema of the optic discs

On this grading there were 31 cases of malignant hypertension with papillœdema (grade 4), 39 cases of angiospastic retinitis with hæmorrhages and exudates (grade 3), and 24 cases with grade-1 and grade-2 retinal changes

Results

All these cases have been carefully followed, and the 30 which were operated on five or more years ago have been analysed to give the survival-rates shown in fig 1 In this chart the figures for medically treated cases reported by Keith, Wagener, and Barker (1939) have been superimposed for comparison, and our results bear out the conclusions reached by Smithwick (1951) on the value of surgical treatment These first 30 patients include 1 in grade 4, who cannot be traced for the last two years and is regarded as having died

TABLE II—METHOD OF DETERMINING NUMERICAL GRADE OF HYPERTENSION

Factor	Numerical value
Example I	
Abnormal electrocardiogram	1
Cerebrovascular accident without residue	1
Phenolsulphonephthalein excretion 20% in 15 min	1
Total	3 = Numerical grade
Example II	
Abnormal electrocardiogram	1
Enlarged heart	1
Phenosulphonephthalein excretion 10% in 15 min	3
Total	5 = Numerical grade

In the grade-4 cases there is a five-year mortality-rate of nearly 50% and at first sight it seems impossible to predict which patients in this group will benefit most More help, however, is given by a new method of classification devised by Smithwick (1951) which is not based solely on the retinal changes

Smithwick's New Classification

A numerical value is assigned to each of a number of significant factors that may be found in these cases (table I) and the patient's numerical grade is the sum of the numerical values of the factors found in his case, as shown in table II By this new system, taking account of factors other than retinal changes, Smithwick classifies his cases in four groups, as shown in table III

For assessing the prognosis in any particular case, we have found this system far more satisfactory than grading by retinal appearances alone It resembles a method of grading suggested by Northfield (1948)

In our comparatively small number of cases (a hundred-odd against nearly six hundred of Smithwick) we have observed that papillœdema is not necessarily the worst prognostic sign, and, when they were reviewed on Smithwick's classification, it was found that his group 4 was a far more accurate indication of prognosis than the retinal grade 4 For example, in our cases 65% of retinal grade 4 and 90% of retinal grade 3 were alive three years after operation, whereas on Smithwick's grading the figures would have been 45% of group 4 and 80%

disease ingestion of antibiotics has an adrenocorticomimetic effect,[6] part of which is mineralocorticoid [7] and may cause severe electrolyte imbalance. During the past four years we have refined our antibiotic ingestion schedule, and we would suggest that Mr. MacGregor and Dr. Lewis, or anyone intending to employ any modification of the McGuire-McElhone method, should consider the schedule we have particularly applied to inoperable neoplastic disease.[8]

1. *Type and Dose of Antibiotic.*—McGuire and McElhone use aureomycin hydrochloride in conventional doses. We never use the mycin hydrochlorides, because we too originally encountered severe gastro-intestinal upset with them. We employ either terramycin *base* or streptomycin cobaltochlorophyllinate, neither of which markedly affects intestinal-tract pH. Since our purpose is to reduce intestinal bacterial proteolysis, our dose seldom exceeds 100 mg. daily.

2. *Choice and Dose of Corticotherapeutic Agent.*—A pronounced corticomimetic effect will follow antibiotic administration in any subject with adaptation disease, whose adrenals still respond to stimulation. Where this effect is predominantly mineralocorticoid (deoxycortone-like) cortisone is given in small dosage (12·5 to 50 mg. daily) until the mineralocorticoid preponderance subsides. We never employ A.C.T.H., because all available preparations of it unduly stimulate production of mineralocorticoid.

3. *Treatment of the Patient.*—Treatment cannot be rigidly formalised, and our "schedule" [8] is only useful in that it illustrates the complications likely to arise from exhibition of antibiotics in adaptation disease and how these are to be circumvented. It points out that transfusion of packed red cells will be better borne by these subjects than will transfusion of whole blood, and why. It stipulates avoidance, if possible, of opiates or barbiturates. This does not mean that we permit cancer patients to remain in pain, either physical or mental. The former is immediately brought under control by appropriate nerve-block or—where no other alternative presents—by chordotomy or leucotomy. The latter merits special mention because in any adaptation disease part of the stress is often emotional. Having seen acute leukæmic children doomed by the atmosphere of death around them, we have applied what was learnt in that connection to the management of the cancer patient, of his family, and—sometimes more important—of his attending physician. We refuse to acknowledge to any of these that there is such a thing as a "hopeless" or "terminal" cancer case, and instead we take a positive attitude of hopefulness. The greater part of treatment effort is spent convincing the patient that he will soon be back at work and continue there during a normal life-span. And primarily because of this, he not infrequently does return to work.

The tone of editorial comment on cancer research in this country begins to show a discreet modulation of the brass section that has been blaring out the virtues of "cytotoxic" therapies, including irrational radiotherapy and extensively destructive surgery. The departures suggested by McGuire and McElhone's report may thus get a more impartial hearing. There is nothing new about palliative or sustentive régimes for the cancer patient, and in the light of present knowledge there is reason to believe that results claimed by the Freund-Kaminer school,[9] first in Austria and later at the Pearson Research Institute in England, as well as the Revici group [10] now in the United States, were genuine. These workers approached the cancer patient as a subject of what we would now call a disease of adaptation. In their employment of what was to them available as antibiotic or adrenocorticomimetic agents, they appear refreshingly modern. Anyone interested in the patient with cancer might learn something from them, as we have done.

THE TREASURES OF BARTS

SIR,—Your annotation of May 23 suggests that the renterer of Barts, who between 1420 and 1460 copied the deeds of the hospital, would have valued the "indenture signed and sealed by Henry VIII giving the hospital to the Mayor and Commonalty and Citisens of London." I doubt it.

Up to 1535 there were in London four hospitals, all of them well endowed. Soon all four were emptied; the staff turned out; the endowments taken away. So the poor and the sick had no hospitals. Henry gave back one of the hospitals, St. Bartholomew, but retained the endowments. On his deathbed he regranted the hospital buildings and most (not all) of the endowments; he became the "Founder." This is stated in R. W. Chamber's *Thomas Moore*; he cites in support Norman Moore's *History of St. Bartholomew's Hospital*, vol. II, p. 126.

Amsterdam. TH. H. SCHLICHLING.

BLOOD-GROUPS AND REPRODUCTION

SIR,—Further evidence in support of the suggestion that the blood-groups A and O are less unlike than A and B in reproductive characteristics has come to light from the data of Bryce et al.[1] and Boorman.[2] Boorman's data are drawn from 2000 mother-infant combinations, and Kirk et al.[3] have pointed out that, in this sample, mothers whose latest infant was A-incompatible show, on the average, a steady and substantial fall in fertility with increasing age relative to mothers whose latest infant was compatible (mostly mothers of O infants); they are much more fertile than the mothers of compatible infants below the age of 20, and much less fertile than them above the age of 40.

TABLE I—AVERAGE PARITY OF MOTHERS OF ABO-INCOMPATIBLE INFANTS (BOORMAN)

Over-all average parity	Group of latest infant	Age-group of mothers whose latest infant was ABO-incompatible				
		14–19	20–29	30–34	35–39	40–49
1·92	B	1·00	1·41	2·36	3·00	5·00
1·77	A	1·43	1·37	2·14	2·75	2·91

But the data also show that this age-difference is even greater between mothers of A-incompatible infants and mothers of B-incompatible infants; the details of these two types of mother are given in table I. If this were confirmed it would indicate changes with age in the relative fertility of B, O, and A fathers as well as mothers.

TABLE II—RATIO OF OBSERVED TO EXPECTED MOTHERS

Mothers of the same group as their latest infant				Mothers of a different group from their latest infant				
Data of Bryce et al.		Data of Boorman				Data of Bryce et al.		
Group	Observed/expected	Group	Observed/expected		Group	Observed/expected	Group	
AB	1·17	O	1·01	1·08	B	1·06	B	
O	1·02	A	1·01	1·05	AB	0·99	AB	
A	0·99	AB	0·93	0·92	A	0·99	A	
B	0·96	B	0·85	0·92	O	0·97	O	

The over-all ratio of observed to expected mothers in Boorman's sample is 1·03 for AB mothers, 1·00 for O mothers, 1·00 for A mothers, and 0·99 for B mothers, while in Bryce et al.'s sample of 7856 mother-infant combinations the ratio is 1·02 for AB mothers, 1·01 for B mothers, 1·00 for O, mothers and 0·99 for A mothers, the average parity being 2·43. But

3. Kirk, R. L., Kirk, M., Stenhouse, N. S. *Brit. J. prev. soc. Med.* 1953, 7, 1.

of group 3 Using Smithwick's classification 26 of our cases qualify for group 4 as opposed to 31 placed in retinal grade 4

The excretion of phenosulphonephthalein (P S P) has not been estimated hitherto in our cases, and we have adopted equivalents of renal function as estimated by urea excretion tests as follows

P S P excretion less than 25% in 15 min = 83% normal renal function

P S P excretion less than 20% in 15 min = 66 6% normal renal function

P S P excretion less than 15% in 15 min = less than 50% renal function

Smithwick's own results are shown in fig 3, which compares survivals after dorso-lumbar sympathectomy with survivals in cases treated medically (Keith et al 1939)

The Operation

In all our cases the surgical technique was based on that of Smithwick (1940) This involves section of the diaphragm and removal of the sympathetic chain from D8 or D9 down to below L3, with all the splanchnic nerves, and a careful dissection and removal of the cœliac ganglion As complete an ablation of this ganglion and its many filaments to the adrenals as possible is considered to be an important part of the operation, producing the effects of a partial bilateral adrenalectomy (fig 2) To test this we have on several occasions combined bilateral partial adrenalectomy with the procedure described above, but it is too early to reach any conclusions about the value or otherwise of this step

TABLE III—CLASSIFICATION OF HYPERTENSION

Group	Numerical grade	—
1	Less than 4	Eyegrounds grade 0 or 1
2	Less than 4	Eyegrounds grade 0 or 1 with changes in cerebral cardiac, and/or renal areas, eyegrounds grade 2 3, or 4, with or without *changes in cerebral, cardiac, and/or renal areas*
3	4 or more	Resting diastolic blood pressure less than 140 mm Hg, changes present in cerebral cardiac and/or renal areas but do not include (1) cerebrovascular accident with severe residue (2) frank congestive heart failure, or (3) phenolsulphonephthalein excretion less than 15% in 15 min associated with poor response to sedation
4	4 or more	(1) Resting diastolic blood pressure less than 140 mm Hg, combined with one or more of the following (1) cerebrovascular accident with severe residue (2) frank congestive *heart failure, or (3) phenolsulphonephthalein excretion* less than 15% in 15 min associated with poor response to sedation (2) Resting diastolic blood pressure 140 mm Hg or more

Anatomical studies of the innervation of the kidney and adrenal glands show that their nerves pass from the cœliac ganglion and the upper two lumbar ganglia, hence, removal of the splanchnic nerves and the sympathetic chain from D9 or D10 to L2 should effectively denervate the kidneys and adrenals

Great care is taken to avoid opening the pleura There is no doubt that morbidity is lessened by this precaution No attempt is made to attain high levels of section in the thorax Any arteriolar release achieved in the thorax is slight compared with that produced in the splanchnic, lumbar, and leg areas, and the only real advantage of Smithwick's over Adson's sub diaphragmatic approach is, I believe, that all the splanchnic nerves can be easily identified This is particularly important where the greater splanchnic nerve is hidden in the adventitia of the aorta and only emerges for a short distance to end in the cœliac ganglion Postoperative complications are now uncommon The only severe one, a persistent neuralgic pain extending down to the iliac fossæ, is avoided by sharp section and removal of an adequate length of the subcostal nerve to ensure its not being involved in scar tissue

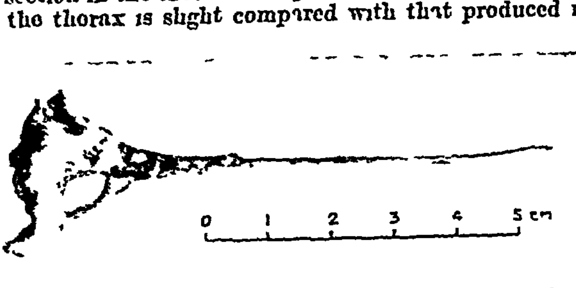

Fig 2—Ablated left cœliac ganglion with its filaments to adrenals.

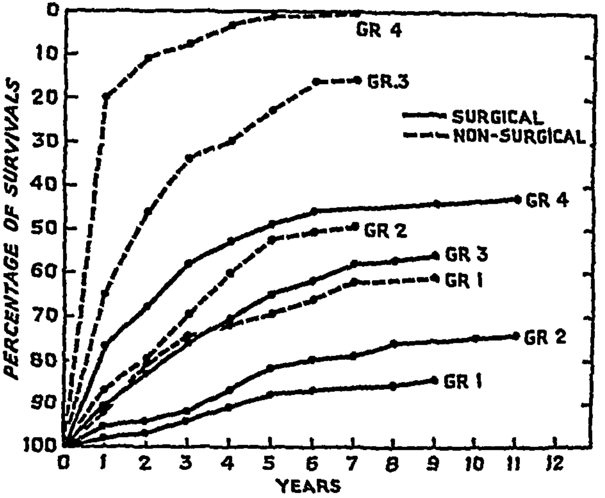

Fig 3—Smithwick s series Comparison of results in 538 cases treated surgically with results in 411 cases treated medically (Keith et al 1939, Smithwick 1951)

Hypertension and Pregnancy

It has always been taken for granted that pregnancy in severe hypertension is a great danger, and early termination is usually advised In dealing with diseases we do not completely understand it is, however, sometimes useful to question time honoured opinions based only on general grounds and the 3 cases described below may be a pointer to new ideas on hypertension

Case 1 —Mrs A , aged 30, was admitted in June, 1947, with a blood pressure of 230/155 mm Hg, severe grade 3 hypertensive retinitis, and some enlargement of the left ventricle but with a good renal function She presented with blurring of vision She underwent bilateral lumbodorsal *sympathectomy and was discharged on July 28, 1947*, with a blood pressure of 145/110 Fig 4 shows her retinal appearances before and after operation

A year later, 1948, she married and at follow up was found to have no symptoms and to have good eyesight and retinæ normal except for slight arteriosclerosis Her blood pressure had, however, risen to 195/125 In 1949 she became pregnant Her blood pressure decreased during early pregnancy, and she had a normal delivery on Feb 28, 1950, of a healthy female child, who is now aged 3 The patient attended recently, when her blood pressure was 190/130, and her retinæ were unchanged more than five years since her operation

Case 2 —Mrs B , aged 34, was admitted in April, 1951, with a blood pressure of 190/135 mm Hg, grade 3 retinitis, and an enlarged heart, which showed electrocardiographically abnormal hypertensive changes Her renal function was normal She complained of headaches during the past three years and of steadily progressive deterioration of vision She had been married several years and had been anxious to have a child Bilateral lumbodorsal sympathectomy was done in two stages in April The blood pressure decreased to 140/100 in June, and the retinæ cleared She became pregnant for the first time at the end of 1951 Fig 5 shows her progress recorded by the sphygmomanometer Labour was induced by the obstetrical department by rupturing the membranes, and she was delivered of a normal female child on Aug 15 last year She has no symptoms and says she has never felt better

TABLE III—RATIO OF OBSERVED TO EXPECTED MOTHER-INFANT COMBINATIONS (BRYCE ET AL.)

Infants ex mothers	Observed/expected	Infants ex mothers	Observed/expected	Infants ex mothers	Observed/expected
—	—	A ex B	1·23	—	—
O ex B	1·08	B ex A	1·20	A ex AB	1·04
B ex O	1·04	AB ex AB	1·17	B ex AB	0·93
O ex A	1·00	O ex O	1·02	AB ex B	0·84
A ex O	0·95	A ex A	0·99	AB ex A	0·78
—	—	B ex B	0·96	—	—

in both samples, as is seen in table II, the descending order of the ratios of observed to expected mothers is O-A-B when the mother and her latest infant are of the same group, and the reverse when the mother and her latest infant are of different groups. In three of the four divisions of table II the difference between the B and A mothers is greater than the difference between the A and O mothers; and that this is not due to the smallness of the number of group-B mothers is suggested by the fact that in the same three divisions the ratio of observed to expected AB mothers—an even smaller number—lies between that of B and A mothers.

Bryce et al. reckoned the amount of variation within their sample (it is greater than that found in Boorman's sample) to be statistically significant. They also pointed out that their excess of A infants of B mothers and of B infants of A mothers, and their shortage of AB infants of A and B mothers, is repeated in Boorman's sample; their own excess of A infants of B mothers, and their shortage of AB infants of A mothers, were so large as to be significant in themselves, and their excess of B infants of A mothers was very nearly so. But the similarity of the samples is even more striking when one compares their 14 individual classes of mother-infant combination, and it is convenient, and also genetically legitimate, to divide these into the groups shown in table III. This gives the ratios of observed to expected mother-infant combinations in the sample of Bryce et al., and the descending orders of ratios seen here are repeated in Boorman's very much smaller sample with two exceptions—transposition of B ex O and A ex O and the placing of AB ex AB between A ex A and B ex B.

TABLE IV—RATIO OF ABORTIONS TO STILLBIRTHS (KIRK ET AL.)

Over-all abortion-stillbirth ratio	Group of mothers	Age-group of mothers of abortions and stillbirths					
		Up to 20	21–25	26–30	31–35	36–40	Over 40
2·66	O	2·10	3·09	4·00	1·85	2·75	1·30
2·38	A	1·40	2·48	3·92	1·78	1·47	1·80

But perhaps the most notable feature of the sample of Bryce et al. is that the highest of the ratios of observed to expected mother-infant combinations are found in the only three classes consisting of heterozygous infants of heterozygous mothers, the over-all ratio for these three classes being 1·21 and for the other classes 0·99, while the corresponding ratios for Boorman's sample are 1·24 and 0·99. Should the same result appear in further samples it might then be worth while considering whether the high frequency of these three classes was due to their heterozygosity giving rise to heterosis or hybrid vigour. In this connection Haldane[4] had said: "It is true that, in the case of (ABO) incompatibility between mother and fœtus, heterozygotes are less fit than homozygotes, but it is unlikely that this influence is enough to counteract the general disadvantage of homozygosis." If this were confirmed it would be interesting to see if the disadvantage of homozygosis was related, in part, to sex.

Boorman's sample unavoidably excluded many abortions and also many normal multiparæ, and that this may be important is suggested by the data of Kirk et al. on 3750 Rh-positive O and A mothers. In this sample, as is seen in table IV, the ratio of abortions to stillbirths is higher for O mothers than for A mothers in every five-year age-group up to the age of 40; and if the same result appeared in further samples greater differences might be found between A and B mothers, and the possible effect of the mothers' Rh group would need to be considered. Moreover, Kirk et al. pointed out that their ratio of O to A primiparæ is significantly higher than their ratio of O to A multiparæ, there being a marked excess of group O primiparæ in every five-year age-group, except 31–35; and here again A and B mothers might show greater differences than would A and O mothers. The sample of Bryce et al. may well have been affected in similar ways.

AN UNUSUAL TYPE OF HERNIA

SIR,—It would seem that an uncommon type of direct inguinal hernia was known to Mr. Hamilton Russell,[1] for he wrote in 1922:

> "There are two kinds of direct inguinal hernia, one of which is caused by a small congenital sac that usually comes straight through the conjoined tendon to project at the external ring. The other form, which is seen with great frequency, consists of a bulging directly through the posterior wall of the inguinal canal internal to the epigastric vessels."

I operated upon my first case on Jan. 7, 1935, and like others have had several examples.

London, W.1.

CAMERON MACLEOD.

THE ILLEGIBLE CANDIDATE

SIR,—The proposal to penalise illegible candidates is a generation too late; in fact, speaking as one who has to contend continuously with illegibility among those who have qualified, I feel that the deducting of marks is not sufficiently severe and only the extreme penalty of failure would have been adequate. However much a doctor may be satisfied with his own bad writing, there appear to be at least two aspects of it which never occur to him. First, it is expensive. If he intends his script to convey information, then the person receiving it has to spend a considerable time in deciphering it and the few seconds (if any) saved to the writer by writing badly involve the reader in maybe as much as half an hour's struggling before any sense can be made of the illegible script. It is the recipient who pays for this, not the writer. In the second place, it is a discourtesy. It never seems to occur to the bad writer that he has the obligation to make his script legible to the person to whom he sends it, and one can only regard bad writing in communications as no less ill-mannered than paying an ordinary social call ill-dressed, unwashed, and with muddy boots.

West Park Hospital, Epsom, Surrey.

W. W. KAY.

A PHILOSOPHY OF MEDICINE

SIR,—Sir Russell Brain's oration to the Medical Society of London, which you published on May 16, is in essence a plea for the outlook which he has summed up in the statement: "Medicine is a branch of biology, and I believe that the philosophy should be based upon a re-examination of the conception of the living organism as a whole." Sir Russell Brain in this statement gives point to the fact, too readily overlooked by investigators, that the human creature developed in its growth and behaviour before the coming of medicine, and that it is in the growth and behaviour of the creature that we must seek for that integrative working principle which, to quote Sir Russell Brain, operates as "a dynamic transaction which itself integrates the activities of the organs."

[4] Haldane, J. B. S. *Ann. Eugen., Lond.* 1950, 15, 15.

[1] *Brit. J. Surg.* 1921–22, 9, 502.

Case 3.—Mrs O., aged 42, was admitted in July, 1948, with a blood pressure of 250/145 mm. Hg and a grade 3 retinitis. She also had been anxious to have a baby but had been sterile. Her sympathectomy was done in two stages at the end of July and the beginning of August, 1948, after which her blood-pressure fell and her retinæ cleared.

Fig. 6 shows her blood pressure over the years since operation and since reporting on Sept. 15, 1952, three months' pregnant. She said she felt better than at any time since the operation. Termination of pregnancy was advised at first by the physicians, but in view of cases 1 and 2 it was agreed to observe her progress and allow her to continue.

Owing to a slight rise in the blood pressure cæsarean section was performed, and she was delivered of a healthy female infant on Feb. 17. She left hospital with a blood pressure of 170/110.

Another patient who underwent sympathectomy elsewhere, is at present under the care of the obstetrical department, which has kindly sent the following notes.

Case 4.—Mrs R., aged 29, in her second pregnancy, expected delivery on Feb. 17, 1953. In December, 1948, she underwent lower segment cæsarean section at thirty weeks for severe pre-eclamptic toxæmia (blood pressure 206/140 mm. Hg, œdema, and ? albuminuria) after failed bougie induction. The baby weighed 2 lb. and lived only forty-eight hours. On the patient's discharge from hospital her blood-pressure was 150/110. On April 9, 1951, she was referred to the Royal Infirmary, Derby, with blood pressure 150/110 and a trace of albuminuria. There was a slight response to 'Sodium amytal.' There was good concentration of the urine. The eyegrounds showed early grade-1 hypertensive fundi. An intravenous pyelogram was normal.

On May 1, 1951, a right lumbodorsal sympathectomy (T4–L3) was done. On July 2, 1951, the blood-pressure was 180/114. On July 3, 1951, a left lumbodorsal sympathectomy was done. The blood pressure level following this operation was not recorded. At the first visit to the Westminster Hospital in July, 1952, when the patient was eight weeks' pregnant, her blood-pressure was 140/110 settling to 130/100 on rest. On Jan. 23, 1953, when she was eight months' pregnant her blood pressure was 120/90 when she was sitting, 110/70 when she was standing, and 150/110 when she was lying down. There was considerable tachycardia, no œdema, and no albuminuria.

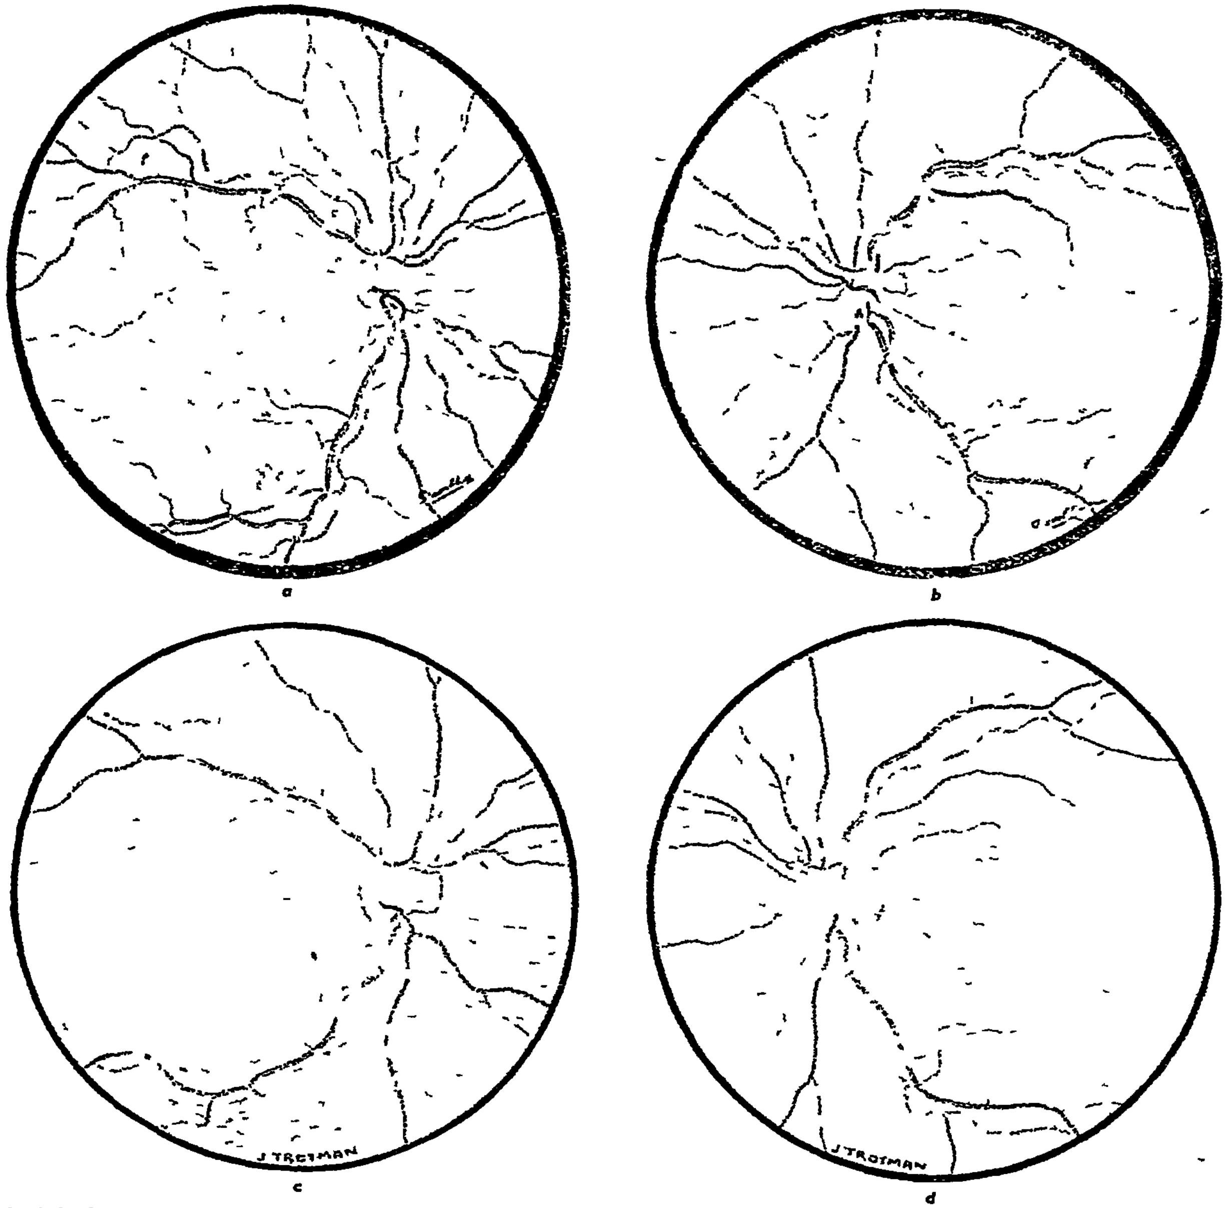

Fig. 4—Retinal appearances in case 1: a, right eye before operation; b, left eye before operation; c, right eye after operation; d, left eye after operation.

The method which enabled Mr. F. Matthias Alexander to discover a directive influence capable of guiding and controlling the living self, so that it operated as an integrated whole and thus as a mechanism working under the influence of what might be called a "dynamic transaction," was the direct experimental observation of the whole living man working as a mechanism in his everyday environment. It is an indication of the limiting influence of specialisation and professionalism that the essential appropriateness of Mr. Alexander's method still awaits recognition by those very persons who profess that what they most desire for men's use and profit are just those very consequences which followed from Mr. Alexander's experiments.

Bolton, Lancs. MUNGO DOUGLAS.

Diary of the Week

JUNE 7 TO 13

Monday, 8th

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. A. L. Cochrane: Medical Field Work.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, W.1
7.30 P.M. Dr. E. Gurney-Clark (New York): Natural History of Acquired Syphilis and its Relationship to Preventive Medicine.

Tuesday, 9th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Dr. H. L. Jaffe (New York): Giant Cell Tumour (Osteoclastoma) of Bone. (Moynihan lecture.)

Saturday, 13th

ASSOCIATION OF CLINICAL BIOCHEMISTS—SOUTHERN ENGLAND AND SOUTH WALES
1.30 P.M. (Courtauld Institute of Biochemistry, Middlesex Hospital Medical School, W.1.) Regional Meeting.

Notes and News

WORLD HEALTH ASSEMBLY

AT the closing session of the sixth World Health Assembly in Geneva on May 22, the retiring director-general, Dr. Brock Chisholm, in a farewell address, reviewed the achievements of W.H.O. since the idea of an international plan for health was first put into practice in 1946. But, he said, we were only at the very beginning of a long and challenging endeavour. Whether the promise of W.H.O. could be fulfilled depended, for one thing, on the participation of *all* nations: health, like peace and security, was indivisible, and the fight against disease could only be won through the concerted effort of all. Five years ago, we had hoped that W.H.O., as a non-political body, could be spared the frustrating effects of a politically *and psychologically* divided world; but it had not been so. And Dr. Chisholm hoped that the universal solidarity which had prevailed at the birth of the organisation would return. Turning to financial handicaps, he said that what W.H.O. was spending on the world's health was no more than the sum laid out by many a large city on its own municipal sanitary arrangements. The organisation's budgets had been and were ridiculously small; and if we were to close the gap which now separated a healthy minority from a majority which continued to live in bondage to disease and misery, then W.H.O. must be given more money with which to play its part.

In carrying out the specialised work of the organisation, there was, Dr. Chisholm thought, a danger of losing sight of the paramount aim for which W.H.O. was created—*namely*, to lay the economic and social foundations for a lasting peace. Clearly, successful health campaigns alone could not promote social progress, for the physically reabled people might merely swell the ranks of the unemployed, dissatisfied, or hungry. The extra labour gained by these campaigns would mean progress only if the people freed from disease were assured of capital investment for production and stabilised markets for distribution, and if they were *guaranteed* sufficient work and adequate educational and cultural facilities for themselves and their children.

Looking at the world scene today, Dr. Chisholm said that man must now learn to live with himself and to reshape his entire pattern of thinking and behaviour in order to build a completely new system of human relationships, adjusted to a changed world. He must realise that ruthless competition, the old rule of survival, had at this stage of scientific and technological development become synonomous with suicide for all of us, and that it had to be replaced by coöperation based on mutual understanding, compromise, and agreement. Dr. Chisholm concluded: "For this generation there is no sane alternative but to accept with courage and determination the realities of a new era. The time for courage, determination, and action, even it may be for martyrdom, is *now*; the place is *here*, wherever we may be and whatever *our responsibilities at the moment*. Every action, every word, works for, or against, the great ideal of peace on earth. We, the peoples of the world, not only in the councils of the nations, but, far more importantly, in our daily living, will decide whether we and our children will live and die in misery and fear far worse than anything we have known, or whether we and they can construct and enjoy a happy and peaceful world community."

THE GENERAL PRACTITIONER

THE Coronation number of the *Practitioner*[1] contains, besides an attractive "pictorial record" of British Medicine, a symposium on General Practice Today and Tomorrow, introduced by Mr. Iain Macleod, the Minister of Health.

The status of the general practitioner, Mr. Macleod says, depends essentially on three things—the trust of his patients, the respect of his colleagues, and the means to do his job adequately. In the last resort all these depend on himself, but there is much that others can do to help him. First, he has a right to be treated by hospital doctors as a colleague and an equal, an essential member of the team.

> "He should have direct access to X-ray and pathological services for his patients, he should receive *prompt* information when his patients leave hospital and, when he refers patients for consultation, he should be sent the mature and considered opinion of a senior

---

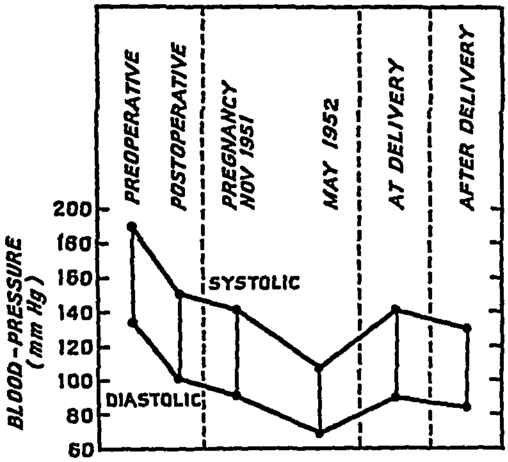

Fig 5—Blood pressure in case 2

On Feb 12 she was delivered of a healthy male child by cæsarean section, and her blood pressure on discharge from hospital was 130/90

The benefit of pregnancy in these cases may be explained either by the circulation of fœtal hormones or by the increase of pelvic circulation due to the arteriovenous shunt in the uterus

Obstetricians say that hypertensives very rarely become pregnant, and this has been regarded as Nature's safeguard in these women against the harmful effects of a pregnancy Without in any way advocating this operation for the cure of sterility, I must point to the fact that pregnancy occurred in 2 of these cases after a long period of infertility, and this may be an indication of the removal of another of the abnormalities produced by the disease

Discussion

Like other stress diseases hypertension is almost certainly on the increase In 1937 the Metropolitan Life Insurance Company of New York stated that half a million deaths took place annually in the United States from hypertension, and that after the age of 45 the death-rate was four times that of cancer and twenty times that of diabetes or of tuberculosis

Thirteen years later Master, Dublin, and Marks (1950) in a report from the statistical bureau of the same life assurance company, made a belated attempt to lift the gloom these figures must have cast by telling us that blood-pressures usually considered above normal were found in about a fifth of the men in their 20s reviewed by them, and that after the age of 45 they are more common than the so called normal blood-pressures These findings do not lessen the seriousness of the figures cited in 1937,

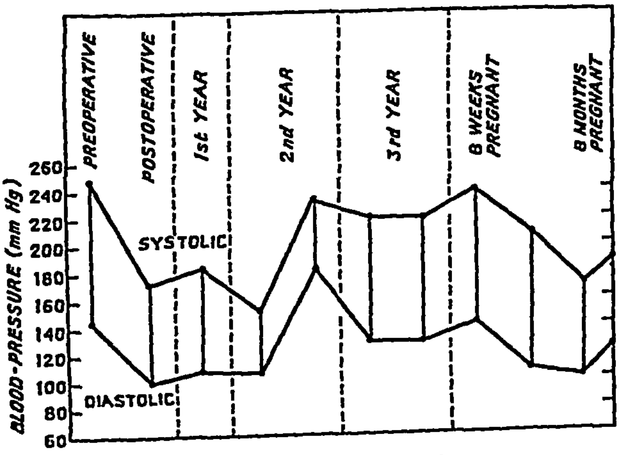

Fig 6—Blood pressure in case 3

but do make it clear that a rise in blood-pressure is not in itself of great importance This is not new in 1925 Sir James Mackenzie said

> "There has been so much nonsense talked and written about high blood pressure that I am constrained to draw attention to our extreme ignorance of the cause and consequence of raised blood pressure That we are totally ignorant of the cause does not prevent many people adopting heroic measures for reducing it, without even considering the wisdom or necessity of so doing That it may be a physiological process for the benefit of the organism is seldom considered It would not be exaggerating to say that the present state of our knowledge of this subject is so wanting in trustworthy data as to warrant neither a sound prognosis nor a rational therapy In some cases it is associated with manifest disease of the arteries or the kidneys, and here a grave prognosis can safely be ventured, but the high blood pressure forms but one datum, and the older physicians could have given as sound a prognosis before the invention of the instrument for estimating the blood pressure"

It is well known that many hypertensives, especially women, tolerate a high blood-pressure without symptoms up to, and beyond, their allotted span However, among these people are those—and we know them to be a very large number—who will die well before their time after severe suffering

There are, it seems to me, three ways of explaining these latter

(1) At some stage the organism begins to deteriorate from the sustained rise in blood pressure, although such deterioration does not seem to be in exact relation to the figure

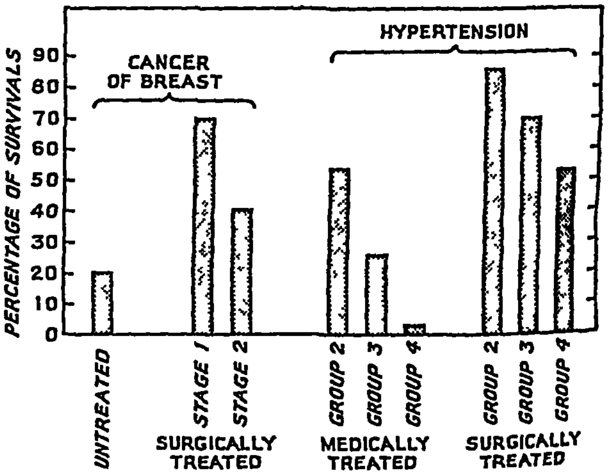

Fig 7—Five-year survival rates in hypertension and in cancer of breast.

obtained—a malignant hypertensive may have lower sphygmomanometer readings than those obtained over several years in benign cases

(2) All the severe cases with a bad prognosis may belong to a separate disease entity—another form of secondary hypertension such as Cushing's syndrome and adrenal *tumour*—but one whose original cause is still unknown

(3) All the patients may be benign hypertensives in whom a new factor has been added to make a relatively normal condition into a fatal one

At present we can only recognise these cases by the damage produced by this new factor, such as retinal, renal, cardiac, and cerebral damage, and their symptoms of headache, disturbance of vision, breathlessness, encephalopathy, or threatened heart failure These are the cases which must be treated with all the resources at our command, whether we choose medicine or surgery

It is wrong and foolish to raise bogies and to spread alarm needlessly, but it is just as reprehensible to ignore dangers and to take no steps to find out the best method of meeting them The insidious threat—what one might call "the underground" in disease—must be attacked just as energetically as the cancerous lump For the member of the staff, not a brief account of findings by a house officer. He should also be made welcome in the hospital if he cares to accompany or visit his patient or to come on a consultant's round. All these requirements are common practice in many parts of the country but there are still hospitals where they are not—to the great detriment of hospital and patient."

The public-health service, too, has a part to play.

> "Just as the consultant has his team of nurses, almoners and medical auxiliaries, so the general practitioner can now have *his* team, organized and made available by the medical officer of health. The district nurse is an old friend and ally, so in many areas is the midwife; but the value of the health visitor has not yet been fully recognized by the general practitioner and her place in his team has still to be worked out."

The general practitioner, for his part, must see to it that he keeps well informed, whether by reading or by post-graduate courses. He must also see to it that the environment in which he sees his patients is such as to inspire respect and confidence. He must reciprocate the coöperation of his colleagues.

> "If these requirements are met, we shall hear less of patients demanding to be sent to hospital because they think that only there can they get the best treatment. We must at all costs break down this attitude for there are many patients for whom hospital care is wrong and that of their own doctor right. This will enable the elaborate and expensive panoply of the hospital to be reserved for those who really need it."

The main subject of the symposium is the means whereby the practitioner can do his job adequately—including his house, his professional premises, his equipment, his dispensary, and his secretarial arrangements.

UP THE REBELS

FROM time to time in every age the image of the noble savage running in wild woods attracts admiring glances. Dr. Robert Lindner is chief consultant to the Board of Correction of the State of Maryland; and his latest book [1] is devoted to proving the necessity for modern man to strive to transcend the limitations of the "triad" consisting of his physical environment, his bodily and mental equipment, and his life-span. According to him, all current institutions, philosophies, and religions direct their efforts to producing adjustment and conformity, and he sees in this the danger that mankind will be reduced to a race of robots, "Mass Man," whose ultimate revolt will be primitive and anarchic and lead to chaos and destruction. He criticises the teachings of many eminent modern American psycho-analysts who in different ways recommend to their patients a passive and resigned attitude: Franz Alexander's concept of the neurosis as a "failure in domestication" of man's hostile impulses, Erich Fromm's and Harry Stack Sullivan's emphasis upon social and cultural factors rather than upon instinctual trends in the genesis of neurosis, and above all Karen Horney's interpretation of neurotic illness in terms of maladjustment to the social environment, come in for some searching criticism.

The individual's dragooning into adjustment begins with the parents encroaching upon his instinctual urges in early infancy in the two important spheres of eating and elimination, and control or suppression of overt sexual behaviour is the next sphere in which the child is made to feel that instinctual life is "bad" if it does not conform to adult requirements. Dr. Lindner feels that most psychologists and psychiatrists, flattered and supported by the seductive approval of the influential section of the community (whose good favour they have so hardly won), unconsciously tend to support its claim that the individual must conform to its mores. Many of the methods of present-day psychiatry—confinement in State hospitals, electro-shock, and, above all, lobotomy—may then be regarded as punitive measures against the "rebel."

Dr. Lindner gives an interesting account of human history in terms of psycho-analysis. He sees the expanding society as one where the frontier serves not only as a zone to which the bad and lawless elements resort, but also as a growing-point. When the frontier becomes rigid, both these types of "rebel" return to the centre of the society and a process of decline sets in. This is controlled at first by an oligarchy, which encourages the proletarianisation of the deprived classes and buys their support with bread and circuses; but sooner or later both the rulers and the masses turn to the Great Man, the symbol of their unconscious desires for primitive and lawless modes of behaviour.

His final chapters offer a prescription which is not easy to follow. He seems to advise that we should educate our children more in accordance with the knowledge we have already gained about man's instinctual endowments; and that psychologists and psycho-analysts should encourage their patients to become "rebels" in an enlightened sense. He is careful to point out that the "rebel" will promote not only his own welfare but that of the community in which he lives; but he seems curiously unaware that it is precisely because man is so uncertain of what his hostile and antisocial impulses might compass that he has, from time immemorial, subjected himself to cultural confines.

WAKLEY AND BARTS

ROUND about St. Bartholomew's Hospital, as a contemporary notes,[1] lie Rahere Street, Paget Street, and Gee Street—all likely enough names for the hospital governors to choose when houses were being built on hospital property. But what, he asks, of Wakley Street, which lies so close beside them? For Thomas Wakley, founder and first editor of THE LANCET, was the avowed enemy of that great Dr. John Abernethy whose forcible character has survived in many a good story, so that it can almost be counted as one of the Barts treasures in itself.[2] Abernethy obtained an injunction against Wakley in the Court of Chancery, for publishing his course of surgical lectures without permission. Surely, the editorial paragraph suggests, the governors would not have named a street after *him*.

That depends, it seems to us, on when the street was built; for the stormy passages between Wakley and Abernethy, that clash of giants, blew up out of a relatively clear sky. When Wakley published his first issue of THE LANCET on Oct. 5, 1823, it was with the open intention of conveying "to the Public, and to distant Practitioners as well as to Students in Medicine and Surgery, reports of the Metropolitan Hospital Lectures"; and he began, in the very first issue, with one of Sir Astley Cooper's lectures. It was an honourable purpose, with a good deal more in it than met the eye, for at that time, as Sir Squire Sprigge, a later LANCET editor, described in his *Life and Times of Thomas Wakley*, a few teachers held a monopoly of students' fees for attendance at lectures, and provincial doctors had no access to what was being taught in London. Moreover though some among the few holders of the rich teaching posts were great figures, some had gained their positions by interest or purchase. Astley Cooper never objected to the publication of his lectures in THE LANCET: he recognised the importance of disseminating medical knowledge and experience, and only stipulated that his name should not be printed. Abernethy was a good deal less dignified in his style than Cooper, peppering his racy lectures with: "I'll be hanged. . . ." "Egad. . . ." and the like; and he was irritated to find these mannerisms faithfully reported. Moreover, like Wakley he was a natural fighter, and willingly took the lead on behalf of smaller men whom Wakley had alarmed by his accurate reporting. The harmonious relations established between THE LANCET and the teachers by the liberal views of Cooper were thus transformed to a battle royal, with Abernethy as champion of the teachers and Wakley as champion of the profession at large; and the first ten years of our now relatively sedate journal were enlivened by ten court actions. Nevertheless when the battle-cries died down, it may well be that the governors of Barts conceded that Wakley deserved a street beside Paget, Gee, and even Rahere himself; and smiling named one for him.

University of Oxford

In a congregation held on May 26 a statute was promulgated giving effect to the decision reached on March 10 (see *Lancet*, March 21, 1953, p. 605) to raise the retiring age of holders of academic posts from 65 to 67. Holders of administrative posts will not be included in the new scheme.

International Congress for Physical Therapy

The first congress of the World Confederation for Physical Therapy is to be held in London from Sept. 7 to 12. Mr. Iain Macleod, the Minister of Health, will open the congress, and the speakers will include Mr. Herbert Seddon, Dr. Herman Kabat (California), Dr. Hugh Burt, Dr. Wallace Graham (Toronto), Sir Clement Price Thomas, Mr. L. W. Plewes, and Dr. F. S. Cooksey. Further particulars may be had from the secretary of the Chartered Society of Physiotherapy, Tavistock House (South), Tavistock Square, W.C.1.

latter there are accepted surgical treatments which are by no means necessarily a cure, or even the ultimate best method, but they are the best at our disposal They prolong life and alleviate suffering

Hypertension is more prevalent and more fatal than many forms of cancer, and a standardised treatment is long overdue Whether this should be by drugs or by surgery cannot yet be finally decided, there being no five year figures for the treatment with methonium compounds as there are for lumbodorsal sympathectomy, but I contend that, if the same approach were made to hypertension as is made to cancer, the evidence we have at present would establish surgery to be as obligatory in the severe cases as a radical mastectomy is for early carcinoma of the breast

It is instructive to compare the severe form of hypertension with that of cancer of the breast In both conditions the ultimate outcome of untreated cases can be predicted with reasonable certainty In cancer of the breast there are universally established methods of treatment which are not condemned because in many cases they do not cure the patient Their value lies in the proof of five-year or ten-year cures and the removal of a lump which, if untreated, would cause much suffering

Fig 7 shows the five-year survival-rates for untreated and surgically treated cancer of the breast compared with the five-year results in medically and surgically treated hypertension The figure for untreated carcinoma of the breast is the mean of the upper and lower figures given by Shimkin (1951) The figure for the results of surgical treatment is based on the recent review of cases at the Cancer Hospital by Professor Smithers (1952) and is the average survival-rate for all grades of malignancy in stages 1 and 2 of breast cancer The figures for hypertension are taken: (*a*) for the non-surgical cases, from Keith et al.'s (1939) cases added to Smithwick's (1951) cases who refused surgery, and (*b*) for those treated surgically, from Smithwick's (1951) figures Assuming that Smithwick's figures are correct, it is obvious that if the condition under consideration were some form of cancer instead of hypertension, the need for surgery would be generally accepted Smithwick has shown quite clearly, in a series far larger than any reported in this country, that the prognosis for patients with hypertensive cardiovascular disease, ranging from slight to severe, is significantly improved by sympathectomy.

Surgical treatment of hypertension cannot be condemned because it does not guarantee a permanent cure Yet it *is* commonly condemned because the blood-pressure often returns to its preoperative level, even though symptoms remain in abeyance and more certain evidence of improvement is visible in the fundi and in the size of the heart (Harland and d'Abreu 1949) Physicians, I venture, tend to become the slaves of their sphygmomanometers The relief of crippling headaches and the restoration of normal sight to one going blind cannot be dismissed as mere relief of symptoms and as no indication that the progress of the disease has been decreased or even halted

Conclusion

A raised blood-pressure is a common finding in many normal healthy people and in itself may be unimportant If it is accompanied by evidence of damage to the cardiovascular system or to the renal system it becomes a disease with a high and early mortality Such cases should be treated with the best resources at our command.

On present evidence surgery offers the best chance of prolongation of life Moreover it removes very serious and crippling symptoms and allows the patient to return to work—a very important point in the type of person commonly afflicted. The old-fashioned methods of complete rest alone may, by their frustrating effects, accelerate the fatal course of the disease, whose progress should be judged not by the sphygmomanometer but by the information provided by cardiac efficiency, the retinae, and renal function Judgment of the new methonium compounds must await five-year results in each group to compare with those of surgery

The object of this article is to survey those cases with evidence of damage indicating a poor prognosis which have undergone operation, and to put forward our findings on the assessment of these cases and the effects of surgical treatment Their analysis bears out the findings of Smithwick and emboldens one to say that, in the present state of our knowledge, we are as justified in counselling lumbodorsal sympathectomy in a case of severe hypertension which has not progressed to a hopeless stage and is not over the age-limit as we are in advising radical mastectomy in a case of stage-1 or stage 2 cancer of the breast

I acknowledge gratefully the great help given me in providing material for this paper by the physicians of the Westminster Hospital, particularly Dr C Gavey, and the ophthalmic surgeons and the obstetrical and pathological departments I also wish to thank my surgical registrar, Mr. David Woodhead, F.R.C.S., who has compiled all the follow up findings and helped me in many other ways

DETECTION OF WEAK Rh ANTIBODIES IN MATERNAL ANTENATAL SERA

THE VALUE OF ENZYME-TREATED TEST CELLS

F STRATTON
M.D Manc, D.P.H.
DIRECTOR, BLOOD TRANSFUSION SERVICE, MANCHESTER, SPECIAL LECTURER IN HUMAN SEROLOGY, UNIVERSITY OF MANCHESTER

ANTENATAL Rh typing is performed on a large scale in this country and abroad, and, now that effective methods of treatment are available for hæmolytic disease of the newborn, it is important to know during the antenatal period whether the maternal serum contains Rh antibodies

The majority of mothers whose babies are affected with hæmolytic disease are Rh-negative, and their sera contain Rh antibodies, anti-C + D, and anti-D, or occasionally anti-D + E Rh-positive women may rarely give birth to children affected with hæmolytic disease, in these cases the commonest antibodies are anti-E and anti-c, in that order

In most laboratories the search for Rh antibodies is confined to the sera of mothers who are known to be Rh negative—i e, D-negative In the case of Rh-positive mothers the sera are examined only where the history suggests hæmolytic disease of the newborn

The presence of a Rh antibody in the maternal serum should be considered to be pathological In this Transfusion Service Rh antibodies from about 950 cases have been examined, and in only 1 instance does the evidence suggest that the antibody may be of natural occurrence, there being no evidence of immunisation

It is customary to examine the maternal serum upon the mother's first or second visit to the antenatal clinic

University of London

The degree of D.SC. has been conferred on A. D. M. Greenfield and C. L. Oakley.

The following have passed the final examination for the degrees of M.B., B.S.:

Honours.—J. H. Bulmer, R. Y. Calne, A. F. Champion, M. L. Crosfill, M. J. Hodgson, Homi Feroze Jeejeebhoy, B. S. Jones, Peter Knipe, Caroline S. Koblenzer, Paul Mestitz (university medal), J. L. Turk, T. H. M. Warburton, R. S. Williams, D. A. H. Yates.

Pass.—Jessamine M. Akhurst, D. P. Adamson, B. L. Anderson, Margaret L. Arden, Janet E. Arnott, J. F. Arthur, K. J. Atkins, Bridget K. Attlee, N. J. Badham, Jean F. Baker, Patricia M. Banks, A. R. Royal Society of Arts

The gold Albert medal of the society for 1953 has been awarded to Dr. E. D. Adrian, O.M., P.R.S., for his contributions to neurophysiology.

Linnean Society of London

The Linnean gold medal has been awarded to Prof. P. A. Buxton, F.R.S.

Oliver Award

The committee of the Oliver Memorial Fund intend making a sixth award (£50) to a British subject for original work or services in connection with blood-transfusion. The committee will welcome applications and communications drawing their attention to suitable candidates. Applications must be sent before Aug. 31 to the hon. treasurer, Mr. F. W. Mills, c/o National Provincial Bank Ltd., Holborn Circus, London, E.C.1.

Children and Dangerous Drugs

Branch representatives of the Pharmaceutical Society have asked the Ministry of Health to publicise the importance of tablets and other medicines being kept out of reach of children. They also suggest that, in addition to publishing advertisements, the Ministry should approach the B.B.C.; the television authorities might be asked to produce a documentary illustrating the potency of many of the medicines now being dispensed.

Rodents and Rodent Control

By arrangement with the United States Public Health Service, a series of films illustrating the habits of rodents and the latest methods of rodent control in the United States will be shown at the Royal Sanitary Institute, 90, Buckingham Palace Road, London, S.W.1, on Thursday June 11, at 2.30 P.M. Applications for tickets should be sent to the secretary of the institute as soon as possible.

CORRIGENDA: *Accidents at Home.*—The numbers of deaths from accidents in the home (60,000) and from accidents on the roads (48,000), which we gave on May 30 (p. 1107), were the totals for the period 1940–49 and not the yearly averages.

Cerebral Angiography.—Our leading article of May 16 says that the first carotid angiography in this country was done in 1932 at the National Hospital, Queen Square. We are informed that a case investigated by carotid angiography at Edinburgh in 1929 is illustrated in H.M. Traquair's *Introduction to Clinical Perimetry* (London, 1938; p. 252).

Angiocardiography.—In our leading article of May 30, where we quote the views of Goodwin et al. on the use of angiocardiography in congenital heart-disease, our reference should be to their recent paper on this subject in the *British Journal of Radiology* (Goodwin, J. F., Steiner, R. E., Mounsey, J. P. D., MacGregor, A. G., Wayne, E. J. *Brit. J. Radiol.* 1953, 26, 161).

Appointments

BARNS, T. E. C., M.A., B.M. Oxfd, M.R.C.O.G.: obstetrical specialist, Colonial Medical Service, Malaya.

FARQUHAR, J. B., M.B. Birm., F.R.C.S., M.R.C.O.G.: consultant surgeon (part-time) in obstetrics and gynæcology to the United Leeds Hospitals and to other Leeds hospitals under the Leeds R.H.B.

WATKIN, JAMES, H.C., M.B. Lond.: part-time asst. (S.H.M.O.), department of psychiatry, St. George's Hospital, London.

WHEILDON, ALICE, M.B. Melb., M.R.C.O.G.: asst. M.O., Finchley and Hendon area.

Manchester Regional Hospital Board:

CAPPER, J. I., M.B. Leeds: tuberculosis physician and M.O., mass miniature radiography unit, Preston.

DIXON, R. I., M.R.C.S., D.A.: consultant anæsthetist, Barrow and Furness hospital centre.

KARFOOT, A. K., M.B. Manc., D.A.: consultant anæsthetist, Barrow and Furness hospital centre.

SLATER, H. B., M.B. Manc.: tuberculosis physician, Oldham and Ashton hospital centres.

North East Metropolitan Regional Hospital Board:

AMULREE, Lord, M.A., M.D. Camb., F.R.C.P.: part-time geriatrician (consultant), St. Matthew's Hospital, London.

FRANCE, N. E., M.B. Wales: full-time pathologist (consultant), Queen Elizabeth Hospital for Children, London.

TUCK, IVY, M.B. Lond.: full-time pathologist (consultant), St. Margaret's Hospital, Epping.

South Western Regional Hospital Board:

FINN, DENIS, M.B. Lpool: asst. psychiatrist, Horton Road and Coney Hill hospitals, Gloucester.

GALLA, THOMAS, M.B. Edin.: registrar in psychiatry, S.W. region.

HUNTER, R. M. M., M.B., B.SC. Edin., M.R.C.P., D.P.H., D.P.M.: consultant psychiatrist, N. Gloucestershire clinical area.

LINTON, C. D., M.B. Brist., D.OBST.: anæsthetic registrar, Southmead Hospital, Bristol.

SCHWARTZ, SAMUEL, M.B. Cape Town, F.R.C.S.E.: orthopædic registrar, Winford Orthopædic Hospital, near Bristol.

WALKER, W. L., M.B. Aberd., D.P.H., D.P.M.: senior registrar in mental deficiency and child psychiatry, Bristol clinical area.

and, if no antibodies are found, to repeat the test during the seventh or eighth month of pregnancy In some instances Rh antibodies are very weak and difficult to detect, especially during the first three months of pregnancy but also in some sera on the second examination during the later months of pregnancy Rh-positive children born to mothers whose sera contain such Rh antibodies are often mildly affected, for example, the only evidence of abnormality may be a positive Coombs test on the cord-blood or, coupled with this, hæmatological changes but no clinical sign of hæmolytic disease Nevertheless this is not invariably so, and mothers whose sera contain such weak antibodies may give birth to children who are severely affected with the disease Weak Rh antibodies present during the early antenatal period may increase in strength during the later months The danger here is that only a single sample of blood, obtained early in pregnancy, is available for testing Owing to the inadequacy of the tests or the manner in which they are performed, these weak Rh antibodies may, at this stage, go undetected and the mother be delivered at home, hence, there may be delay in diagnosis and treatment prejudicial to the child's complete recovery

Exchange transfusion is now carried out at birth, in certain circumstances, as the treatment of choice in hæmolytic disease Diamond et al (1951) and Mollison (1951) have laid down the conditions under which exchange transfusion should be done It has also been shown that exchange transfusion is an effective method of treatment in these conditions and diminishes or abolishes the chances of kernicterus

If Rh antibodies are present in the maternal serum, the mother's pregnancy and delivery should be observed and hæmatological and serological observations should be made on the cord-blood at the time of birth in case there should be the need for an exchange transfusion If no indications for treatment are present, the child should be observed both clinically and hæmatologically during the ensuing weeks, so that treatment may be instituted before a desperate or dangerous situation develops

It is therefore of considerable importance to know in advance whether the maternal serum contains Rh antibodies, even though these may be weak

I report here the results obtained in 200 cases recently studied in which Rh antibodies were detected, and describe the value of the slide technique with enzyme-treated test cells as a screening method for the detection of these antibodies, especially the very weak Rh antibodies

Technical Methods

There are four main tests for detecting the presence of Rh antibodies in sera

1 Agglutination test in saline
2 Agglutination test in albumin.
3 Antiglobulin, or Coombs test
4 Enzyme treated cell test

In these tests the serum is examined with Rh-positive cells used as test cells I shall not give technical details of the first three of these tests, because they have been described by Mollison et al (1952) In all these methods suitable control tests are necessary, especially in the antiglobulin or Coombs test In my laboratory this test is done on microscope slides, a reading being made and recorded at 2 4, and 6 minutes If the test is negative Rh sensitised cells are added to the slide to make sure that the Coombs reagent is active

PREPARATION AND USE OF ENZYME-TREATED CELLS

Group O Rh positive cells of type $R_1 \left(\begin{smallmatrix}CDe/CDe\\CDe/cde\end{smallmatrix}\right)$ and $R_2 \left(\begin{smallmatrix}cDE/cDE\\cDE/cde\end{smallmatrix}\right)$ are collected in acid citrate dextrose (A C D) mixture, four volumes of whole blood to one volume of A C.D mixture—i e, similar to the proportions of anticoagulant and blood in a 500-ml bottle These cells are washed three times in physiological saline solution, and one volume of washed packed red cells is mixed with one volume of papain buffer mixture consisting of equal parts of papain and buffer solution, and with one volume of activator The mixture is incubated in a water bath for 10 minutes at 37°C The cells are spun down, and the supernatant fluid is removed, the cells are then washed once in physiological saline When the cells are being washed, violent shaking should be avoided These cells are referred to as papainised cells 1–2 ml of washed packed cells is normally prepared

The papainised cells are freshly prepared on alternate days, although they can be stored for 1 or 2 days in saline solution in the refrigerator Experiments with methods for prolonging the preservation of papainised cells in the refrigerator and with the preservation of them frozen solid in glycerol have given encouraging results and will be reported elsewhere

The papain buffer and activator solutions are prepared as follows

Papain —Papain (dry powder, B D H) 1 g, saline solution 100 ml

Buffer —Disodium hydrogen phosphate 12 H_2O 3 6 g, water 100 ml

Activator —L cysteine hydrochloride 0 2 g, saline solution 100 ml

The papain solution is best preserved frozen solid The activator solution is freshly prepared The solutions are kept separately, and the buffer is mixed with the papain, and one volume of this is added to one v ume of activator and one volume of packed cells incubation in the water-bath

The test is performed on a microscope sli temperature One volume of a 10% sus papainised cells in saline solution is mixe volume of the serum under test, the latter with physiological saline, making the final the serum 1 4 Alternatively, a volume o *serum and a volume of saline solution* can together, and two volumes of cell suspensi The slides are gently rocked for seven min results may be read under the lower power of scope but are clearly visible through a hand cavity plastic tile can be used instead of a gl *scope slide, but it is a less sensitive* met results of the test are scored as follows

+ + + + − = Massi no free cel
+ + + + = Very with a few
+ + − = Many with mo
clearly visible
+ − = Multiple clumps of 6–8 cells with man
just visible to the naked eye
+ = Small clumps of cells with many free
through a hand lens

The patients' sera were usually 24 hours old whe

With each batch of tests controls are put up c of a mixture of papainised cells and normal ser a group-AB donor and diluted 1 2 in saline This is to ascertain that the cells are not spon agglutinable

Each batch of papainised cells is tested wit selected incomplete Rh antibody to see that t equally strongly treated on each occasion of this standard antibody by various meth R_1R_2 (CDe/cDE) test cells are shown in table I particular Rh antibody, in a dilution of 1 100, result visible to the naked eye should be obtaine strength of the agglutination will depend on the sc of the test cells and varies from + − to + + +

Rh antibodies are demonstrable at 37°C as at room temperature, but a number of positive appear at room-temperature which are not pr 37°C, although occasionally false positive res

ACETYLCHOLINE AND THE HEART BEAT*

J. H. BURN
M.D. Camb., F.R.S.
PROFESSOR OF PHARMACOLOGY IN THE
UNIVERSITY OF OXFORD

IN considering the relation of acetylcholine to the heart beat we think first of all of the action of the vagus nerve. When stimulated, the vagus liberates acetylcholine, and this diminishes the rate and force of the beat. Since cardiac muscle resembles skeletal muscle in being striated muscle, the action of acetylcholine on cardiac muscle is anomalous, for acetylcholine stimulates skeletal muscle, and it might therefore be expected to stimulate cardiac muscle also. Why then does it inhibit cardiac muscle?

The action of quinidine on cardiac muscle raises the same question. Quinidine is used to restore the normal sinus rhythm in auricular fibrillation. According to Prinzmetal et al. (1952) auricular fibrillation is due to the discharge of impulses at a very high rate from an ectopic focus, and the effect of quinidine is to diminish the rate of discharge to such a point that the sinus node resumes its function as pacemaker. Now quinidine, like procaine and quinine, is a substance which has been shown to antagonise the action of acetylcholine in all forms of muscle (Dawes 1946). Thus in the presence of quinidine a given concentration of acetylcholine has much less effect in stimulating both the frog rectus muscle and the rabbit intestine and in inhibiting the heart. Quinidine thus raises the threshold for acetylcholine. The action of quinidine in diminishing the rate of discharge of an ectopic focus in fibrillation would be explained if the discharge was actually initiated by acetylcholine. Thus we come back to the question why acetylcholine, so far from initiating a discharge of impulses, normally has the opposite effect and inhibits the rate and force of the beat.

The suggestion had already been made, briefly, by Koshtojanz (1938) but notably by Abdon (1945), that acetylcholine plays a part in the contraction of cardiac muscle. Neither of these workers was able to demonstrate that acetylcholine stimulated the heart to beat; and, so long as the only known action of acetylcholine was to inhibit the heart, it did not seem that serious attention could be given to this view. Attempts were therefore made by us to discover conditions in which acetylcholine stimulated cardiac muscle.

Experiments

ACTION OF PROGUANIL ON THE HEART

Many of our observations were made on the auricles of the rabbit heart. When the heart is excised, the auricles can be dissected from other tissue and suspended in a well-oxygenated bath of Locke's solution at 29°C. They beat spontaneously, and the contractions can be recorded on a drum by a light lever. The rate of beating varies from 80 to 150 per minute.

During a study of the pharmacological action of the antimalarial substance proguanil ('Paludrine') the observation was made that, when added to the bath containing the beating auricles, proguanil in a concentration of 10^{-4} (1 g. in 10,000 ml., or 1 mg. in 10 ml.) gradually reduced the amplitude of the contractions and after 30–40 minutes caused the contractions to stop. The beat was not resumed during the next 30–40 minutes. If, however, acetylcholine was added to the bath in a concentration of 10^{-6}, the beat began again and continued until the acetylcholine was removed, when it stopped once more. When acetylcholine restarted the beat, further additions of acetylcholine augmented the amplitude (Burn and Vane 1949).

ACTION OF ACETYLCHOLINE ON STOPPED AURICLES

The significance of these observations was not clear, since the changes in cardiac tissue caused by proguanil were unknown. The question arose of demonstrating a stimulant action of acetylcholine without proguanil. My colleague, Dr. Edith Bülbring, was able to to this by allowing the auricles to beat in the bath for 24–30 hours, during which time the contractions became feebler and stopped spontaneously. She found that the addition of acetylcholine in concentrations of 10^{-7}–10^{-6} caused the beat to begin again and to become fairly vigorous in 15–30 minutes. The beat then continued for some time after the acetylcholine was removed. This demonstration clearly established that acetylcholine had two actions, one the stimulation of the exhausted auricles, and the other the well-known inhibition of the auricles when set up fresh in the bath. Moreover, both actions were observed in the same preparation: the first addition of acetylcholine caused the beat to begin again; the next addition increased both the amplitude and the rate; and a further addition then caused inhibition. The demonstration that in certain circumstances acetylcholine stimulated the auricles made the hypothesis seem much more likely that a local production of acetylcholine caused the heart beat.

It may be noted at this point that the concentrations of acetylcholine used to start the beat of the stopped auricles were low—much lower than those found by Hoffmann et al. (1945) to stimulate the heart after treatment with atropine. This is a different action of acetylcholine which, when studied in the auricles, has been found by Kottegoda (1953) to be exerted only by concentrations of acetylcholine as high as 10^{-5}–10^{-4} and to be prevented by hexamethonium. Thus it appears to be a ganglionic action, distinct from the action of acetylcholine in starting the beat of stopped auricles which is effected in concentrations of 10^{-7}–10^{-6} and which appears to be exerted on the cardiac tissue itself.

THE CHOLINE-ACETYLASE SYSTEM

If the contractions of auricles are maintained by the synthesis of acetylcholine, we might expect in the first place to find acetylcholine present in the auricles. Recent determinations in the Oxford laboratory by Briscoe and Trendelenburg gave a mean result of 4·8 µg. of acetylcholine per gramme of fresh tissue.

The synthesis of acetylcholine is effected by choline acetylase, and Comline (1946) found this enzyme present in rabbit auricles. This enzyme converts the inactive substance choline to acetylcholine, energy being provided by adenosine triphosphate, and acetyl groups coming from citrate. We determined the activity in freshly excised auricles (Bülbring and Burn 1949) by preparing an acetone-dried powder, which was incubated according to the procedure of Feldberg and Mann (1946). At the end of incubation acetylcholine was found to be present and was estimated on the frog rectus muscle by comparison with a solution of acetylcholine of known strength. The amount of acetylcholine formed was expressed per gramme of acetone powder per 75 minutes, which was the time of incubation. Having made observations on freshly excised auricles, we made other observations on auricles which had ceased to beat after being suspended in the isolated organ bath for 24–30 hours, and finally we made observations on auricles which, having ceased to beat, were stimulated by acetylcholine to resume the beat. The results of this investigation are given in table I and show that the choline-acetylase activity of the auricles which had ceased to beat was much lower than that of fresh auricles.

---

* A lecture given in the University of Oslo on March 25, 1953.

TABLE I—TITRES OF STANDARD ANTIBODY IN VARIOUS TESTS

Test	Dilutions of standard anti Rh serum									
	1/2	1/4	1/8	1/16	1/32	1/64	1/128	1/256	1/512	Control
Albumin agglutination	+++++	+++++	+++	+	−	−	−	−	−	Neg
Coombs	+++++	+++++	+++++	+++++	+++	++	−	−	−	Neg
Papainised-cell	+++++	+++++	+++++	++++	++++	+++	++	+	−	Neg

appear at 37°C If a positive reaction is obtained at room-temperature, the test should be repeated at 37°C by placing the freshly prepared cell serum-saline mixture in a capillary slant either in a water-bath or in an incubator at 37°C or on a warm viewing-box If agglutination is still present at 37°C, the serum should be examined to confirm that a Rh antibody is present This is done by testing it with its own cells and with Rh-positive and Rh-negative cells, the latter selected to contain all other blood-group antigens

Occasionally antibodies are detected at 37°C with papainised cells, which are auto antibodies These will react with the patient's own papainised cells and with Rh-negative papainised cells, they are therefore usually readily identifiable as such If it is thought that Rh antibodies are occurring together with auto-antibodies, which is extremely rare, the serum should be absorbed with the patient's own papainised cells and re examined

Results

The results of testing 200 Rh antibodies from D-negative mothers are shown in table II The results are those obtained in testing the first sample of maternal serum received in that particular case The results of testing, of course, may alter during pregnancy, but, since second samples may not be available, it is important to consider the results obtained with the first sample received This table is compiled on the assumption that the Coombs or antiglobulin test is used in combination with the saline agglutination test If these two tests are used together, only a very small proportion of antibodies (about 1%) will remain undetected This variety of antibody is very uncommon, and in the two cases referred to in table II second samples obtained at a later date gave a positive Coombs test If the albumin test is used alone on the first sample received, 7% of antibodies will remain undetected, if more than one examination of the maternal serum is undertaken, it is probable that, even so, about 5% of antibodies would be missed if this method alone were used All the sera tested by the papainised-cell technique described above gave a positive result This applied to those sera which gave results by only one of the other methods described (classes III and IV)

The frequency of false positive results with the papainised cell technique was determined by the examination of sera from Rh-positive persons 1264 sera, obtained from the blood of Rh-positive healthy donors of all ABO groups, were tested with Rh-positive papainised cells on microscope slides at room-temperature, 28 positive results were found 16 out of the 28 were visible only on microscopy, and only 3 of these 28 were still active at 37°C with the papainised test cells when tested in capillary slants These 3 sera were also active with Rh negative papainised cells and with their own papainised cells at 37°C, no Rh antibodies were detected If microscopy of the test is used, therefore, the number of false positive results will be about 2%, but, if a hand lens is used, this would not amount to more than 1% In the technique used it is recommended that all positive results should be repeated at 37°C in capillary slants, and, when this was done, only 3 of 1264 sera showed false positive results, about 0 25% Moreover these can readily be distinguished from true anti-D antibodies

Comments

It is useful to consider whether there are any general technical details which will assist in the detection of weak Rh antibodies Firstly, the specimen from the patient should be freshly collected and free from antiseptics Sometimes it is advantageous, especially with the saline agglutination test, to inactivate the serum at 56°C for 25 minutes before use Secondly, the selection of sensitive test cells is most important All Rh-positive cells are not equally sensitive when used for the detection of anti-D antibodies, and it has usually been found that Rh-positive cells of type R_2r (cDE/cde) or R_2R_2 (cDE/cDE) are more sensitive than cells selected from most other genotypes This will be seen, for example, in table III, and, although the antiserum may react more strongly with cells of these types, or with cells of type R_1R_2 (CDe/cDE), or weakly or negatively with cells of type R_1R_1 (CDe/CDe), the serum does not contain an anti-E antibody, indeed such sera gave negative results with $R''r$ (cdE/cde) cells In preparing enzyme-treated cells and in selecting cells for doing other Rh tests,

TABLE II—RESULTS OF TESTING 200 Rh ANTIBODIES FROM D NEGATIVE MOTHERS

Class	Tests		No tested
I	Saline agglutination	+	121 (*60 5%*)
	Albumin agglutination	+

	40	12	40
	47	18	38
Mean	46	7	37

While this result was not surprising, the much higher values for auricles which had begun to beat again when stimulated by acetylcholine showed that the choline-acetylase activity was related to the rhythmic contractions. The results in table I provided direct evidence for the view that acetylcholine is synthesised in the auricles, and that, when a threshold concentration is reached the acetylcholine initiates the wave of contraction perhaps in the same way as in skeletal muscle; in so doing the acetylcholine is destroyed and the building up of the concentration begins again.

THE ACTION OF THE VAGUS

When acetylcholine is added to the bath containing the contracting auricles, the amplitude of the contractions is decreased and the rate of beating is slowed. It occurred to us that this inhibitory action might be due to a depression of the synthesis. We therefore tested the effect of adding acetylcholine to the tube in which the acetone-dried powder prepared from the auricles was incubated in the course of determining the choline-acetylase activity. In carrying out these experiments we mixed powder prepared from four or five auricles and distributed portions weighing 50 mg. in a series of tubes. One of these was incubated in the usual way as a control tube, and to the others acetylcholine was added in amounts corresponding to 5, 10, 20, 40, and 80 µg. per gramme of powder before incubation. In all, 17 experiments were made, and each experiment showed that the presence of acetylcholine partially inhibited the action of choline acetylase. When the values in each experiment were expressed as a percentage of the synthesis in the control tube, mean values could be calculated (table II). These results indicate that the action of acetylcholine in slowing the rate and decreasing the force of the beat is accompanied by and may in part be due to the depression of the synthesis of acetylcholine.

THE ACTION OF ESERINE

The destruction of acetylcholine is due to the action of cholinesterase. Ord and Thompson (1950) have found that in the auricles of the rat both true and pseudo-cholinesterase are present, the proportion of the latter being greater than that of the former. An investigation of the action of eserine, which inhibits the action of cholinesterase, was therefore undertaken (Burn and Kottegoda 1953). Concentrations varying from 10^{-8} to 10^{-3} of eserine sulphate were tested, the effect being observed for 30 minutes. Even the lowest concentration affected both rate and amplitude, the rate being usually decreased and the amplitude always increased. When higher concentrations were used, the effects were greater though in the same direction, until the auricles were exposed to a concentration of 10^{-3}. This depressed the amplitude and after a few minutes arrested the contractions (see fig. 1). The mean effects of different concentrations are shown in table III.

TABLE II—INHIBITORY ACTION OF ACETYLCHOLINE ON SYNTHESIS OF ACETYLCHOLINE BY RABBIT AURICLES
Mean of 17 experiments

—	Amount of acetylcholine added (µg. per g. of auricle powder)				
	5	10	20	40	80
Percentage of control synthesis	71	70	55	54	30

These results of the effect of eserine on the auricles are by themselves strong evidence that the rhythmic contractions are maintained by the formation of acetylcholine within the auricular tissue. The evidence that a low concentration of eserine modified the contractions clearly indicates that the cholinesterase present in the auricles exercises a control of the rhythmic activity, for eserine in a concentration of 10^{-8} presumably acts only by inhibiting cholinesterase—i.e., by reducing the rate of destruction of acetylcholine. The increase in amplitude caused by concentrations from 10^{-8} to 10^{-4} therefore showed that, by progressively reducing the rate of destruction of acetylcholine, the force of the contraction was steadily increased. When, however, the rate of destruction was slowed still further by a concentration of 10^{-3}, the force of contraction was reduced, with the result that at this point the concentration of acetylcholine appeared to be in excess of the optimal concentration for the force of contraction.

While eserine thus augmented the amplitude in low concentration and depressed it in high concentration, the mean effect on the rate was depression with all concentrations. A double effect on the rate was, however, seen in several preparations, the lowest concentrations increasing the rate and higher ones decreasing it. Moreover, in a series of perfused frog hearts it was observed that the usual effect of eserine in concentrations of 10^{-7} and 10^{-6} was to increase the rate. Thus the observations showed that eserine could increase the rate of contraction just as it increased the force of contraction, though the point at which a further increase of concentration decreased the rate occurred much sooner. Thus the evidence indicated that the optimal concentration of acetylcholine for the highest rate of beat was not related to the optimal concentration for the greatest force of beat.

TABLE III—EFFECT OF ESERINE SULPHATE APPLIED FOR 30 MINUTES ON RABBIT AURICLES

Concentration of eserine (g. per ml.)	No. of experiments	Percentage change	
		Rate	Amplitude
10^{-8}	6	−6	+12
10^{-7}	6	−10	+27
10^{-6}	9	−22	+16
10^{-5}	11	−18	+40
10^{-4}	14	−32	+58
10^{-3}	7	Arrest	−57

ARREST OF THE BEAT

In a concentration of 10^{-3} eserine arrested the beat in a few minutes; the beat recommenced when the fluid in the bath was changed. Since the concentration was so high, this effect of eserine might have been due to some other action than that of an anticholinesterase. We found, however, that, when auricles had been beating in a bath overnight, the effect of lower concentrations of eserine, such as 10^{-5}, was much greater. Whereas this concentration depressed the rate of a group of seven fresh auricles by a mean figure of −7%, it depressed the rate of a group of five auricles beating from 20 to 24 hours by −58%. My colleagues E. Bülbring, H. J. Shelley, and S. R. Kottegoda have found that when auricles have been beating in Locke's solution for this length of time they lose pseudocholinesterase without any loss of "true" cholinesterase. Thus the effect of a therefore, it is an advantage to select at least some of the cells from group R_2r (cDE/cde) or R_2R_2 (cDE/cDE), but even within this group not all cells are equally sensitive

The period of pregnancy during which the sample of serum is obtained is important Many sera obtained early in pregnancy contain weak Rh antibodies only, and these may be stronger in later months, although this is not invariably so Several cases have been seen, however, in which the antibodies did not appear until the end of the seventh or during the eighth month of pregnancy It seems advisable, therefore, if the maternal serum does not contain antibodies at the beginning of a pregnancy, for it to be re examined a second time not earlier than the eighth month

Many methods have been described using enzyme treated cells for detecting Rh antibodies (Morton and Pickles 1951, Rosenfield and Vogel 1951, Wiener and Katz 1951), but they involve a technique done at 37°C The advantage of the present method is that it permits the test to be done rapidly on microscope slides at room-temperature

I shall not discuss here the effect of pH on the papainisation of red cells or the various activators that could be used in their preparation, or the fact that the difference in the manner in which the blood is collected affects the degree of papainisation of the red cells (Stratton 1953)

The papainised-cell technique is valuable in that unlike the saline and albumin agglutination and Coombs tests, it can be used alone and, so far as can be ascertained from the results detailed above, will detect all types of Rh antibody Investigation of sera containing Rh antibodies which gave a weakly positive result with the Coombs test alone (table II, class III) showed that good positive results were obtained with the papainised-cell slide technique, and this method appears to be as sensitive as the Coombs test Occasionally a positive papainised cell test has been obtained where the routine Coombs test was negative, however, if the Coombs test was repeated with single group O Rh-positive cells of specially selected genotypes, in contradistinction to the routine test in which mixed group-O Rh-positive cells of unknown genotypes are used, positive results were obtained (table III) In certain other cases (Stratton and Stone 1953) sera were found which gave a positive papainised-cell test before the Coombs test was positive

One of the disadvantages of any technique using enzyme-treated cells is that there is a tendency for false positive results to be obtained, particularly if the test is done at room-temperature This is partly due to the presence of naturally occurring and other specific antibodies in the sera and to the occurrence in certain sera of an auto antibody to enzyme-treated cells (see below) It is to be noted that the phenomenon of Rosenthal and Schwartz (1951) obtained when trypsinised cells are used does not always occur when papainised cells are used The papainised-cell slide test is very sensitive and gives few false positive results, even though done at room temperature This is attributable to the high degree of enzyme treatment given to the cells, making them very sensitive (which is achieved by the use of the enzyme activator), coupled with the dilution of the maternal serum 1 2 before the test

Occasionally auto agglutinins to enzyme-treated cells are present in normal sera The circumstance of a combination of Rh antibody and auto agglutinin present in the same serum has not been met so far in testing Such a combination of antibodies might be suspected if the results of testing with Rh positive papainised cells are much stronger than similarly treated Rh negative ones The rouleau-forming property of certain antenatal sera has not caused difficulties in this test, but, if sera are tested which have very strong rouleau-forming properties, aggregation of enzyme treated cells will take place Since the test is done in a saline medium, microscopy might suggest or confirm the presence of the rouleau formation In a recent case, in which the serum showed very strong rouleau-forming properties, aggregation did take place with enzyme treated cells, when the serum was diluted 1 3 instead of 1 2 and the papainised cells were added, the rouleau formation was abolished The test is so sensitive that it is very doubtful whether, if a Rh antibody were present together with this severe rouleau formation, its detection would be prevented by a serum dilution of 1 3

This enzyme cell slide technique is designed especially for the purpose of detecting Rh antibodies and is intended to be used as a screening test Certain specific antibodies may give a positive result at room-temperature with this technique, although rarely at 37°C, for example, anti P and anti Lewis are detected at room-temperature, but these antibodies usually do not give positive results in capillaries at 37°C, anti Kell antibodies may give a positive result in capillaries at 37°C As stated already, therefore, it is important that the nature of the antibody should be confirmed The term "false positive" result is used here for the sake of simplicity and is intended to mean a positive result which does not indicate the presence of a Rh antibody at 37°C The incidence of these is about 2% at room temperature, but they are of rare occurrence at 37°C

Summary

The importance of weak Rh antibodies is considered, and various factors concerned in their detection are described and discussed

A slide technique using papainised cells for the detection *of Rh antibodies is described*

This slide technique is shown to be sensitive, and suitable for use as a screening test

With an increasing awareness of the consequences of ureterocolic anastomosis there has arisen a dissatisfaction with the results of this operation Serious renal complications have developed not only as immediate sequelæ but also months or years after an apparently successful transplantation Attacks of pyelonephritis are common, and, together with dilatation of the kidney pelvis and of the ureters, they are associated with various degrees of renal damage Recent investigations have shown that these complications are frequent and figure prominently among the causes of death following this operation It has also been shown that, after ureterocolostomy, serious biochemical disturbances may arise, of which hyperchloræmic acidosis and uræmia are the most likely

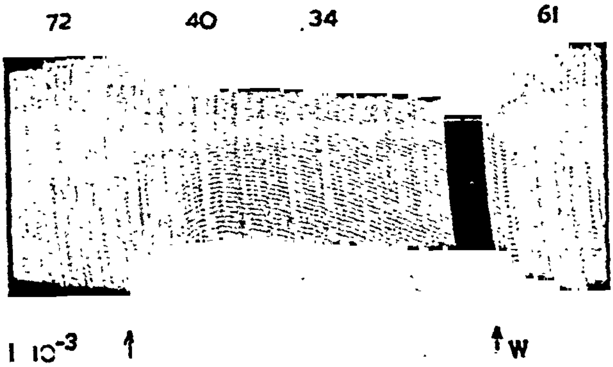

Fig. 1—Record of spontaneous contractions of isolated rabbit auricles in Locke's solution. Rate 72 per minute at 29°C. Addition of eserine to bath to make a concentration of 1 mg. per ml. (E10^{-3}) slowed rate to 40 after 2 minutes and to 34 in 5 minutes. Contractions stopped after 8 minutes. Beat started again when eserine was washed out (W).

given concentration of eserine on the rate of auricular contractions depends on the amount of pseudocholinesterase present, and the evidence points to the conclusion that concentrations as high as 10^{-3} cause the arrest of fresh auricles simply by inhibition of cholinesterase. The substance di-*iso*propylfluorophosphonate affects the rate of beating in the same way as does eserine, causing arrest of the beat in concentrations from 10^{-3} to 5×10^{-3} Molar.

ACTION OF ESERINE IN HEART-LUNG PREPARATION

Dr. J. M. Walker and I have recently studied the action of eserine in the heart-lung preparation of the dog prepared by Starling's method. The medullary centres are excluded from the circulation, and the vagi are cut; so that there is no central control of the heart-rate, which depends on the impulses from the sinus node. The addition of eserine to the reservoir of blood (0·6 mg. in 600 ml.) to make a concentration of 10^{-6} caused the rate to fall. This fall was, in one experiment, from 122 per minute to 64 per minute in 10 minutes, at which lower level it remained (see fig. 2). The injection of 10 µg. of atropine sulphate restored the rate to its original level.

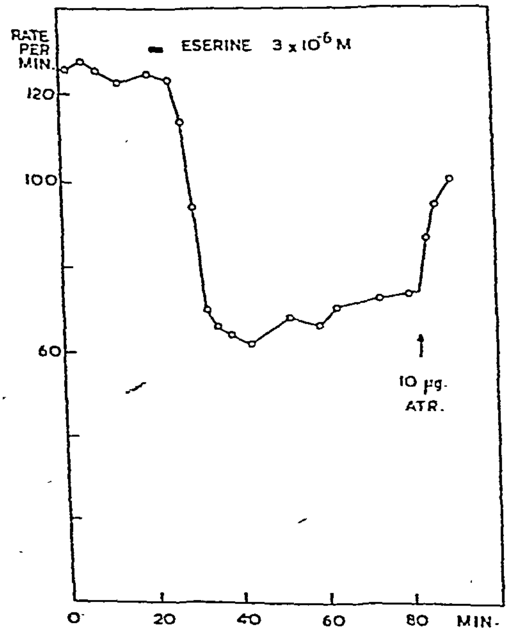

Fig. 2—Heart-rate in dog heart-lung preparation. 600 ml. of blood was in system. When eserine 0·6 mg. was added to the venous reservoir, the rate fell from 124 to 60 per minute. Rate rose when atropine 10 µg. was injected.

To make certain that this effect of eserine was not due to the presence of the vagal nerve-endings from which it was conceivable that some acetylcholine might still be liberated, we tested the effect of eserine in preparations made from dogs in which the vagi had been cut four days previously. Though larger amounts of eserine were necessary, the same decrease in the rate was observed when eserine was added to the blood, and the rate was again restored by atropine. Thus, when the cholinesterase in the heart was inhibited, the rate slowed. The only deduction which can be made from this observation is that the rate is governed by the production of acetylcholine which in the presence of eserine accumulates. Since the effect was seen 96 hours after section of the vagus nerves, the acetylcholine cannot have been liberated at the vagus endings.

IRREGULARITIES OF BEAT

The evidence thus far obtained indicated that there were conditions in which acetylcholine stimulated the rate and force of the beat and also conditions in which it depressed the rate and force of the beat. Eserine also exerted the same dual action. These observations are consistent with the view that the initiation of the beat is due to the formation of acetylcholine, which fires the conducted disturbance when its concentration reaches a certain threshold. On this view irregularities of the beat would be likely to be associated with irregularities of acetylcholine formation and would be modified by the application of acetylcholine or of eserine.

A systematic study of irregularity has not been made, because we do not know how to produce it at will. The effect of eserine was, however, observed in the isolated auricles, some preparations of which beat irregularly. In a concentration of 10^{-5} or 10^{-4} eserine was observed to convert an irregular beat to a regular beat. This change was observed sometimes without and sometimes with an accompanying change in amplitude. The change was sometimes accompanied by a slowing of the rate and sometimes by a quickening of the rate (see Burn and Kottegoda 1953). These results suggest that the irregularity was due to an irregular production of acetylcholine, so that sometimes a longer interval and sometimes a shorter interval was required to reach a concentration sufficient to set up the contraction wave. We may suppose that in the presence of eserine the destruction of acetylcholine was slower, and therefore the threshold concentration for the initiation of the contraction wave was always reached in a given time.

In the heart-lung preparation the injection of acetylcholine was found to correct and also to cause irregularity. Thus in a preparation freshly set up a 2 to 1 block persisted for 15 minutes, the auricles beating 152 a minute, and the ventricles beating 76 a minute. Injection of acetylcholine 4 µg. caused the block to disappear. On the other hand, in another preparation, in which eserine had been added to the blood so that the concentration was $1{\cdot}3 \times 10^{-6}$ g. per ml., the injections of 0·1 µg. and of 0·2 µg. of acetylcholine caused not only slowing but also irregularities of the beat.

Discussion

The evidence supports the theory that in the auricles of the heart acetylcholine is produced locally by choline acetylase and initiates a contraction when its concentration reaches a threshold value. The acetylcholine is then destroyed by cholinesterase, and the rate and force of the beat seem to be dependent on the balance between these two enzymes.

When Grey Turner (1929) reported the results of this operation in a detailed account of the progress of his patients he showed that many of them had unpleasant and serious complications He said that he was convinced that most of his patients developed some degree of ascending infection, and in the two necropsies that were performed there was definite and gross evidence of its existence, although neither patient had had symptoms indicating its presence He emphasised, however, his belief that a moderate degree of renal infection is not incompatible with average good health

It is plain from the reports of cases of long survival that the operation can yield good results there are instances of patients who have lived many years after transplantation of the ureters into the colon Nevertheless analyses of large series of cases, especially the comprehensive investigation made for the British Association of Urological Surgeons by Jacobs and Stirling (1952) clearly indicate that in general the long-term results are by no means satisfactory, at least half the patients have attacks of pyelonephritis, many have evidence of renal damage, and fully 80% show biochemical abnormalities Acidosis, demonstrated by an alkali reserve below the limit of the normal range, is found in 80–85% of patients A much smaller group show clinical evidence of acidosis that may end in coma and death

Because of the dissatisfaction felt with the standard operations of Stiles (1911) and Coffey (1911) there have recently been attempts to prevent stenosis at the ureterocolic junction (Nesbit 1949, Cordonnier 1949, Leadbetter 1951), but it is becoming plain that these have neither materially affected the incidence of ascending infection in the kidneys nor reduced the number of deaths from renal causes

Apart from recurrence of the disease for which the ureterocolic anastomosis is done, three factors seem responsible for many of the unhappy results

(1) Ascending infection with recurring attacks of pyelonephritis, ureteritis, and secondary stricture formation

(2) Primary stenosis at the site of the ureterocolic anastomosis, with hydronephrosis and renal destruction

(3) Biochemical disturbances probably caused by the absorption of urinary waste products from the large bowel, in association with renal damage

Each of these is a direct consequence of the implantation of the ureters into the large bowel

Cutaneous ureterostomy has been done successfully for many years, but the difficulty of collecting urine from two small stomata has led to its being little used Schnagel and Sewell (1948) have described the creation of spout ureterostomies in an effort to overcome this difficulty, but there has been no wide application of this method

After some experimental work in dogs (Annis 1952), in which it was shown that the small bowel could be used quite satisfactorily to take the place of, and act as, a ureter, we used a length of ileum, isolated from the intestinal tract, to collect urine from the ureters and to carry it to the skin-surface, where it drained into an ileostomy bag This operation was performed in patients who otherwise would have had a ureterocolic anastomosis The proximal end of this isolated length of ileum was closed, and the ureters were implanted into it The distal end protruded through a stab incision, and a Rutzen-type adhesive ileostomy bag was fitted We find that Bricker (1950) described a similar operation, but it was done as an alternative to a wet colostomy in patients in whom both the bladder and the rectum were excised He said that the patients were better able to manage a simple colostomy and an "ileostomy" that drained clear urine Our experience with the wet colostomy confirms this, but it has been our impression that biochemical changes occur less often in the patients who have a wet colostomy than after the usual ureterosigmoid anastomosis Perhaps this is because there is less pressure within the colon, and less delay in the expulsion of urine from it Bricker (1950) reported good results in 10 cases done since 1946 the patients were in good health, there was no azotæmia, and the intravenous pyelograms were normal He concluded that there was no justification for attempts to make an artificial bladder after pelvic evisceration when an adhesive bag could be quite manageable and satisfactory

It is too early to assess fully the results in our four cases, but they are encouraging

CASE-RECORDS

Case 1 —A man had a papilliferous tumour completely occupying the bladder

Operation (Professor Wells) —On Jan 4, 1952, the bladder was removed, a length of about 8 in. of ileum was mobilised, and the continuity of the small intestine was restored by end to end anastomosis The upper end of the isolated intestine was closed, and into it each ureter was implanted by direct mucosa to mucosa anastomosis The lower end of the isolated ileum was implanted into the side of the pelvic colon A valve was made at the ileocolic anastomosis in the hope of preventing reflux

Postoperatively the patient was discharged on Jan 28, passing urine from the rectum and feeling very well When he was seen a month later all seemed satisfactory The blood urea level was 33 mg per 100 ml, and the other biochemical factors studied were normal On intravenous pyelography both kidneys appeared normal The side limb of small intestine seemed to be effectively preventing regurgitation from the large bowel into the ureters, but in the course of the next three months the patient developed attacks of pyelitis Although he was in no worse condition than many patients who have had the conventional ureterocolic anastomosis, it became plain that this operation had not prevented ascending renal infection

Second Operation —On June 3 the loop of small intestine was detached from the pelvic colon and brought out as an ileostomy draining urine Since that time there have been no further attacks of pyelitis and the man feels well When seen recently he was having some difficulty in collecting urine from the ileostomy He is quite dry during the day, but there is some leakage at night The ileum was brought out through the lower end of the abdominal incision, and the bag does not fit closely to the skin In the other patients the ileum has been brought out through a separate stab incision, and this difficulty has not been encountered

Case 2 —A man, aged 38, was first seen by us in February, 1952 In 1942 he began to have attacks of frequency and scalding, which continued until, in 1945, he had a left epididymectomy and right nephro ureterectomy for tuberculosis After this operation he developed urinary fistulæ from the nephrectomy scar and a watering can perineum For seven years he had worn napkins to collect the urine and had passed none normally

On examination he was rather thin and pale On the perineum were four or five small openings, all leaking urine Intravenous pyelography showed a distended left ureter which appeared to be obstructed near the bladder, and the left kidney showed pelvic and caliceal hydronephrosis There was a thimble bladder The blood urea level was 26 mg per 100 ml, and a radiograph of the chest was normal No specimen of urine was examined for tubercle bacilli, because it could not be properly collected

Operation (W R Hunter) —On Feb 26, 1952, a low left abdominal incision was made in the shape of an inverted Y, the flap being turned down for the ileostomy A grossly dilated ureter was exposed and divided and about 9 in of the lower ileum 1 ft from the ileocæcal valve was isolated and mobilised with its blood supply intact (fig 1) The bowel was reconstituted by end to-end anastomosis The isolated loop of bowel was sutured end-to end with the ureter in an isoperistaltic fashion (fig 2) The anastomosis was laid on

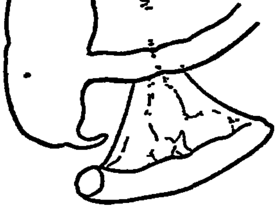

Fig 1.—Isolation of ileal segment

The theory depends in the first place on the demonstration that acetylcholine has more than one action, and that its effect is not merely to diminish the rate and force of the beat as when the vagus is stimulated. Acetylcholine will start the beat of the auricles when it has stopped, and increase the rate and amplitude. Moreover eserine, which inhibits the action of cholinesterase, will increase the rate of the perfused frog heart, and the rate of some preparations of the rabbit auricles. Eserine also increases the force of contraction of rabbit auricles proportionally to its concentration in the range 10^{-8}–10^{-4}. All these observations indicate that acetylcholine can initiate the beat and increase its rate and force.

The usual effect of acetylcholine in depressing the beat appears to be explained by the theory that there is an optimal concentration (or range of concentration) of acetylcholine both for the rate of beat and for the force of the beat. Acetylcholine in excess of this optimal concentration depresses both the rate and the force of the beat, in part by depressing its own synthesis. So far as the rabbit auricles are concerned when isolated and beating in a bath, the optimal concentration of acetylcholine for the most rapid rate of beat is different from that for the greatest force of beat.

The theory agrees well with what is known of the action of quinidine on the heart. This substance is used to restore a normal rhythm in auricular fibrillation. According to Prinzmetal et al. (1952) auricular fibrillation is due to the discharge of impulses at a high rate from an ectopic focus. Quinidine reduces the rate of discharge to such a point that it is less than the rate at which impulses leave the sinus node and the sinus node therefore resumes its normal function. Now quinidine is an antagonist of acetylcholine—i.e., it raises the threshold at which acetylcholine is effective. Its action in reducing the rate of discharge from an ectopic focus is precisely the action to be expected if the discharge is due to the initiation of impulses by the formation of acetylcholine at the ectopic focus. In the presence of quinidine the time taken for acetylcholine to be formed in sufficient concentration to discharge a contraction wave would be prolonged, and so the rate of discharge would fall.

It is probable that acetylcholine is concerned not only with the initiation of the rhythmic contractions but also with the conduction of the impulse and with the force of the contraction. Evidence concerning conduction is provided by the fact that quinidine decreases the rate of conduction, and also by the observations of Prinzmetal and his colleagues that the infusion of acetylcholine into the dog prevents the failure of conduction which otherwise occurs when the heart is driven electrically at very high rates. Evidence concerning the force of the beat is provided by our own observations on the action of eserine in increasing the amplitude of the contractions of the auricles. Further investigation on these points is obviously required.

The formation of acetylcholine in the auricles may take place either in nervous tissue or in non-nervous tissue. In 1924 Gray pointed out how close was the parallelism between the activity of cilia and of the sinus region of the excised frog heart. We have recently shown (Bülbring et al. 1953) that the ciliary movement in the nerve-free gill-plates of the sea-mussel mytilus is controlled by the local production of acetylcholine. The parallelism observed by Gray, then, suggests that in the heart the acetylcholine may also be produced in tissue which is not nervous.

Summary

Evidence is described which shows that the rhythmic contractions of the heart are due to the local production of acetylcholine. This is synthesised by choline acetylase, and when the concentration rises to a threshold value the wave of contraction is initiated. The acetylcholine is then destroyed by cholinesterase.

There appears to be an optimal concentration of acetylcholine for the maintenance of the beat, and amounts in excess of this optimum depress the rate and force of the contraction. This is the effect seen when the vagus nerve is stimulated.

SURGERY IN SEVERE HYPERTENSION

A SURVEY OF RESULTS

FRANK D'ABREU
Ch.M. Birm., F.R.C.S.
ASSISTANT SURGEON, WESTMINSTER HOSPITAL

THE surgical treatment of hypertension demands careful collaboration with a physician, and our experience at the Westminster Hospital shows that, as regards the advisability of operation, physicians and surgeons are not always ranged in opposing camps. Nevertheless surgery has in late years had a bad press in Britain from physicians, as may be seen from the following opinions:

(1) "There is no doubt that sympathectomy sometimes leads to an improvement in the retinæ, renal function, and the electrocardiogram in patients with malignant hypertension, and it is possible that surgery is justified in these patients until medicine has something more satisfactory to offer. However, the overall results in hypertensive disease are disappointing and have been overestimated. This operation should not be advised for the treatment of hypertension other than in its severe and malignant stages" (Brigden 1952).

(2) "If we could only select with certainty those few cases which do respond we should be very pleased to continue recommending sympathectomy, but unfortunately all the preoperative tests to improve selection which have been tried seem to have failed utterly. We must reluctantly admit that a large number of quite useless operations have been performed and that there is very little prospect of any satisfactory improvement in surgical technique or selection in the near future" (McMichael 1952).

(3) "The results of sympathectomy may be briefly summarised by saying that in a very small group of cases the operation will produce results which cannot be obtained by any other means at the present time. It is still extremely difficult to predict the case in which the benefits will be worth while" (Platt 1950).

Against these we have the surgical opinion of Smithwick (1951):

"The evidence available at present indicates quite clearly that the prognosis for patients with hypertensive cardiovascular disease ranging from slight to marked is significantly improved by thoracolumbar splanchnicectomy."

And lastly what we may take to be a neutral opinion in the *British Medical Journal* (1952):

"There is now little doubt that surgical treatment has materially lowered the fatality-rate of hypertension."

the pelvic wall and covered with peritoneum, and the intestine was sutured along the left wall of the pelvis and brought out through the abdominal incision, being sutured to the parietal peritoneum along its length The right hand free edge of the mesentery of the isolated loop was sutured to the anterior abdominal wall A spout ileostomy was made, the skin pedicle being used on the under surface and a split skin graft on the upper surface This is not the ideal arrangement, but, had the incision been made to cover the upper surface with the skin pedicle, the epididymectomy scar would have transected the skin flap The wound was closed snugly round the isolated loop of intestine A rubber catheter was tied into the ileostomy Urine began to collect immediately

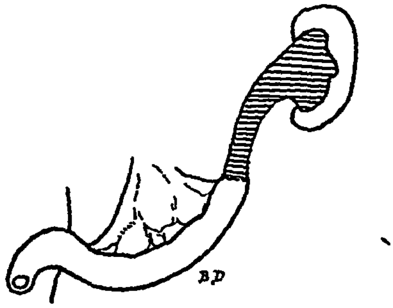

Fig 2—Implantation of single dilated ureter into ileal segment

Result—Convalescence was smooth, and he was discharged from hospital on May 11, after completing a course of streptomycin and *p* aminosalicylic acid All his sinuses were then dry He has remained well and put on 15 lb in weight in nine months All his fistulæ are dry, and urine collects satisfactorily in an ileostomy bag The CO_2 combining power and plasma chloride, plasma sodium, plasma potassium, and blood urea levels are all normal

Case 3—A woman, aged 71, had a papilliferous tumour involving the length of the right ureter and the bladder

Operation (Professor Wells)—On April 1, 1952, the right kidney and ureter and the bladder were removed About 12 in of ileum was isolated with its blood supply intact, and the intestinal continuity was restored by end to end anastomosis The proximal end of the isolated segment was closed and the distal end brought out to the skin surface The remaining ureter was implanted by a direct mucosa to mucosa technique into the upper end of this isolated length of terminal ileum Urine drained from the ileostomy immediately

Result—She made an uninterrupted recovery An adhesive Rutzen type ileostomy bag was applied, and urine collects in it freely When seen six months after the operation, she was very well and active The blood urea level was 32 mg per 100 ml, and the CO_2 combining-power and serum sodium, serum chloride and serum potassium levels were normal An intravenous pyelogram was normal and showed no hydronephrosis (fig 3) Mr H N Daniel, of Lancaster, writes "She is quite happy, comfortable, and doing house work and enjoying her life, and gets about and visits her friends The skin around the ileostomy is healthy and does not appear in any way soggy or excoriated She has a copious flow of clear urine from the ileostomy"

Case 4—A man, aged 44, complained of frequency and lower abdominal pain with hæmaturia for about three months Intravenous pyelography showed good concentration on both sides, with some right hydronephrosis and hydro ureter due to obstruction in its intramural portion There was a filling defect (fig 4) due to a papilliferous neoplasm, occupying the greater part of the bladder Cystoscopy confirmed this, and there were several other small papillomata on the posterior wall and another large one on the left lateral wall Biopsies showed no definite evidence of malignancy, Bimanual examination revealed a mass palpable in the bladder It was decided that nothing short of total cystectomy would be of any avail.

Operation (W R Hunter)—On Oct 23, 1952, through a midline infra umbilical incision a large mass was palpable in the right side of the bladder, but there were no palpable glands in the pelvis and no evidence of extravesical spread About 10 in of the lower ileum, about 1 ft from the ileo cæcal valve, was isolated, and the bowel was reconstructed by end to end anastomosis The proximal end of the isolated loop was closed The distal end was temporarily closed to prevent soiling the wound and was later used for the ileostomy opening The left ureter was isolated and was passed through the pelvic mesocolon and implanted into the isolated segment of small bowel by a modified tunnel procedure The isolated segment of bowel was now sutured along the brim of the pelvis from left to right until the right iliac fossa was reached The right ureter was isolated and was similarly implanted (fig 5) A U shaped incision was made in the right iliac fossa and a skin flap turned up, and after the muscles had been split the distal end of the isolated segment was delivered through the wound With several interrupted sutures the isolated segment of bowel was made to lie snugly in the right iliac fossa The several raw areas on the peritoneal surface were then reperitonealised The loop of ileum outside the abdomen was covered with the skin fashioned from the incision, and split skin grafts were applied to its under surface A catheter was tied into the segment of bowel to drain away urine Total cystectomy was done

Result—The patient's convalescence was smooth and he was discharged from hospital three weeks after the operation He wears an appliance to fit a spout ileostomy Intravenous pyelography five weeks after operation (fig 6) showed both kidneys to be working normally with still a little hydro ureter

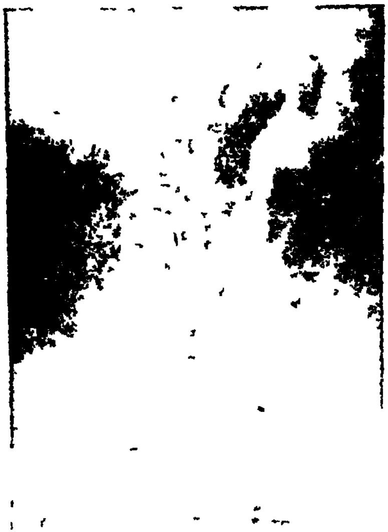

Fig 3—Intravenous pyelogram six months after ablation of right kidney, right ureter and bladder and implantation of left ureter into ileal segment (case 3) Arrow points to ileal segment

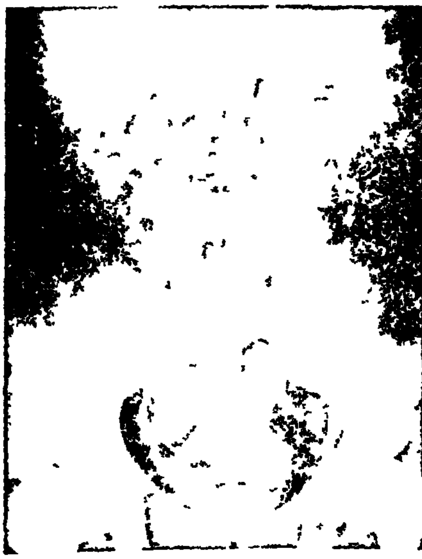

Fig 4—Intravenous pyelogram showing right hydro-ureter due to obstruction by vesical neoplasm (case 4)

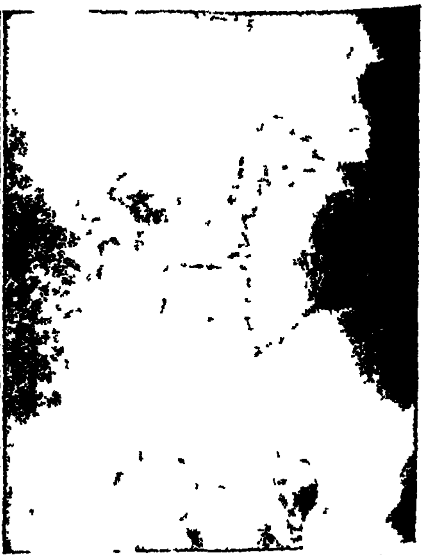

Fig 6—Intravenous pyelogram five weeks after operation (case 4)

ychological and prophylactic effect" of inducing dical experts on both sides to be careful in their sertions and claims, because these might always be viewed by an outstanding authority in their own ld.

For some years the State of Massachusetts has provided, civil proceedings, pre-trial examination of psychiatric ses by impartial medical specialists, and this arrangeent is said to be working well. The result of the ew and far wider experiment in New York may well fluence the development of practice in this country. ndeed, no legislative innovation would be required to troduce a parallel working system here, for under the ules of the Supreme Court (R.S.C. 0·37A, r.1) the court r a judge may already "in his discretion at any time n the application of any party appoint an independent xpert (to be called "the court expert") to enquire and eport upon any question of fact or of opinion not nvolving questions of law or construction." Unfortunately, applications under this rule have been but few nd far between, and it would perhaps be well if judges were given power to call in court experts from an ppropriately prepared list even where no such express equest is forthcoming from the parties.

TREATMENT OF BARBITURATE POISONING

SUICIDAL poisoning with barbiturate drugs is becoming increasingly common,[1] and the mortality may be high even in those who come under medical care. Nilsson in Sweden has shown the value of good medical treatment without convulsant drugs,[2] and Locket and Angus in this country have had similar results.[3] In their series of 84 patients who were not given convulsant drugs there were only 2 deaths. Analeptics are not a treatment for anoxia or asphyxia, and their value is obviously difficult to assess when survival may depend on the skill of the nurse and the doctor in managing an unconscious patient. Nevertheless it has become the practice to give analeptics for barbiturate poisoning because they reduce the mortality in poisoned animals; but then experimental animals do not enjoy the nursing attention that is the patient's right.

In comparing different analeptics the effect of chance on mortality-rates cannot be gauged when deaths are numbered in single figures. Mortality-rates depend on age, individual idiosyncrasy, and the condition of the liver and kidneys, as well as on more obvious factors such as the dose and type of the drug and the amount vomited. Hence little is to be gained from comparing the results of different workers, as Koppanyi and Fazekas[4] have done. They conclude in the end, largely from their own experience, that the best initial treatment is to give 5 ml. of a 10% solution of leptazol. If there is a response to this "orientation dose" they continue with the same dose given every 10 or 15 minutes. Otherwise they give picrotoxin 25 mg. followed by 15 mg. every 15 minutes, provided of course that convulsions are avoided. In general leptazol is more likely to be effective against the rapidly acting barbiturates, and picrotoxin against the slowly acting ones. Koppanyi and Fazekas do not recommend caffeine or nikethamide. Dick[5] discusses 160 reported cases and 11 of his own, all treated with amphetamine; and he favours this analeptic, if only because it is relatively safe. The Council on Pharmacy and Chemistry of the American Medical Association[6] point out that there are deficiencies in investigations of analeptics. Indeed, the evidence for giving picrotoxin at all must be judged inadequate by modern standards; and the cumulative effect of successive doses often means that too much is given, for it has a latent period of up to 30 minutes. On the other hand, leptazol acts quickly and for a short time, and it is often given in inadequate doses.

The use of ultraviolet absorption spectrophotometry has lately provided a satisfactory method of measuring the concentration of barbiturates in body-fluids. Apart from giving much-needed data on the distribution and excretion of barbiturates, this method may facilitate both treatment and diagnosis. By providing a measure of the severity of poisoning, it should make the comparison of the results of different treatments an easier matter.[7] Alwall et al.[8] in Lund have used the method to study means of increasing the elimination of barbiturates. The rapidly acting barbiturates are of course largely destroyed in the healthy liver, but the more slowly acting ones are mainly excreted in the urine. Alwall et al. were remarkably successful in speeding the elimination of phenobarbitone in poisoned rabbits by exchange ultrafiltration and by dialysis. Forced polyuria was less effective. They applied dialysis successfully in two patients, but the full details have not yet been given. Barbiturates are distributed throughout the body-water,[9] and it is unlikely that exchange transfusion[4] can aid elimination effectively; on the other hand where dialysis with an artificial kidney is practicable recovery may probably be hastened in patients poisoned with the longer-acting members of the group. But whether the mortality-rates can be improved with dialysis or with analeptics will remain in doubt until controlled clinical trials have been carried out.

RACIAL PREJUDICE

RACIAL prejudice is a powerful disruptive social force breeding violence and harming every community it touches: and its influence is becoming increasingly apparent in many parts of the world. There is every need therefore to understand its origins, to prevent its spread, and to control its manifestations. Unesco, as the international organisation charged with the spread of peace and goodwill through education, is trying to play its part by calling together a number of sociologists, anthropologists, and geneticists to prepare joint statements on the subject of race, setting out the scientific aspects,[10] and by publishing popular booklets to carry the facts to lay discussion-groups, school-children, and others who may benefit from this information. The latest publication is *What is Race?*[11] which explains the elements of genetics, with a wealth of attractive diagrams, and scientifically refutes some popular ideas of inheritance and the belief in a purer race. The scientists answer the three basic questions—Is there a pure race? Is there a superior race? and are there unchangeable race differences?—with a definite No. The word "race" is used here in the general sense of a group of human beings [illegible] with physically inherited characteristics differentiating [illegible] them from other human beings. But in everyday usage [illegible] race means a good deal more: it means, for instance, the classification of man by nationality, culture, [illegible] which colour [illegible] of his skin; and the class[illegible] may have little to do with his ancestry. [illegible] their own use and [illegible] another word for [illegible] different meaning.

[illegible] Department [illegible] 1952. Organisation [illegible] produced a precipitous drop in the serum-calcium, followed by a gradual return toward normal levels within 6 hours, but when the animals had previously had the thyroid and parathyroid glands removed there was no appreciable return of the serum-calcium towards pre-injection levels The recovery phase of the oxalate-tolerance curve in nephrectomised dogs was, however, found to be the same as that in normal animals, so STEWART and BOWEN concluded that the parathyroid gland exerts a control over serum-calcium that is primarily independent of the kidneys Much other evidence [35] suggests, however, that the ability of P T H to raise the serum-calcium is greatly impaired in the absence of the kidneys, although the animal is then usually in a far from physiological state

DENT [36] has recently driven further nails into the coffin of the Albright theory as the sole explanation of parathyroid action He confirmed that in normal men any phosphorus diuresis after injections of P T H was only slight, and he found that the serum-calcium rose, whereas the serum-phosphorus tended to fall only if it was originally high (as it was in the hypoparathyroid cases studied by ALBRIGHT) Artificial lowering of the serum-phosphorus did not lead to a rise in serum-calcium to maintain the solubility product, and hyperparathyroidism with renal failure and raised serum-phosphorus may be followed by the typical bone changes of von Recklinghausen's disease If ALBRIGHT's suggested sequence of changes were correct, one would expect osteomalacia and not osteitis fibrosa to result Very recently STEWART and BOWEN [37] have shown that preparations of P T H inactivated by formaldehyde with respect to their power to raise the serum calcium still increase the urinary phosphorus output in dogs That this phosphorus diuresis is an artefact is suggested by the similar results when extracts of spleen and thymus are administered DENT [36] has further drawn attention to the apparently irrational dissociation of the bone changes in hyperparathyroidism from the changes in the blood-electrolyte levels, and has suggested (as did L'HEUREUX et al [38] on the basis of electrophoretic studies) that there may be more than one parathyroid hormone, and these may differ in the locus of their actions

It seems clear that parathyroid extracts can act directly on bone and on kidney, and perhaps too much attention has been focused on which of these actions is primary, for the work of MARTIN and PERKINS [39] suggests that P T H may have a quite different primary action MARTIN [40] has obtained data which seem to show that in some cases of hyperparathyroidism the calcium binding power of the serum-albumin is more significantly and consistently increased than in other cases which in turn significantly exceed normal values After surgical treatment of the hyperparathyroidism the calcium-binding power of the serum-albumin usually returns to normal in cases without demonstrable persisting renal damage Perhaps such changes in the calcium-binding power of the body-proteins may explain the metabolic actions of P T H

Annotations

THE COURT EXPERT

IF two doctors were to disagree about a diagnosis, it would be patently absurd to call in a layman to settle the issue between them Yet, as we suggested a year or two ago,[1] something hardly less peculiar happens in legal proceedings whenever irreconcilable opinions are expressed by medical experts engaged by the opposing sides Sometimes, it is true, both parties may accept a written report prepared by a member of the medical profession, but in many important trials whose outcome largely depends on scientific evidence, there is a hiatus in specialist opinion which has to be bridged by judge and/or jury finding their own solution of a technical problem

Medicine being an applied science, it seldom deals with facts from which only one inference is possible Moreover, medical evidence can seldom be visibly and conclusively demonstrated to the court This is true not only where sanity or mental disturbance is in question, but in almost every case where a medical opinion involves forecasts or is the result of laboratory investigation which goes beyond simple observations Being unable to verify his statements, judge and jury must rely on the intelligence and professional conscientiousness of the expert witness Accordingly the court has to concentrate on testing his impartiality and competence

Much interest therefore attaches to an American experiment in which the Supreme Court of New York will appoint court experts other than those chosen by the contesting parties [2] For some time past, United States courts, in dealing with medical expert evidence, have had difficulties similar to those encountered in Great Britain but perhaps even more sharply focused In the United States almost all the testifying is done by a very small proportion of the doctors, and the fees asked sometimes depend on the expert's rhetorical gifts as much as on his professional skill and eminence The preparation of experts' reports for each party, moreover, is one of the principal causes of delay in the disposal of cases where a personal injury has been sustained and where it is necessary to estimate future incapacity In these circumstances, the plan to be tried for a year in New York aims at "better and quicker justice" for the solution of conflicting medical claims, by avoiding the former system under which "a plaintiff's doctor may tend to describe his patient as just about killed while the defendant produces a doctor who hardly finds scratches" The leading professional State organisations the New York Academy of Medicine and the New York County Medical Society, have agreed to appoint a panel of about sixty experts of the highest standing in the various branches of their profession, including orthopedics, neurosurgery, neurology, and psychiatry, on whose knowledge and aid the courts can call whenever the need arises If in the preparation of the trial it is found that the medical claims of the two parties differ widely, the judge will, on his own initiative, assign an expert from the panel to examine the plaintiff and to provide a written report which will be available both to the court and to the two parties This expert is not a referee such as we have in this country under the Workmen's Compensation Acts His report is not binding on the court, nor are the parties precluded from cross-examining the expert in person at the trial or from calling in other experts of their own choosing, though it is expected that the court expert's report will often be accepted by all concerned, since it offers from the outset high guarantee of impartiality and competence Finally it is hoped that the new system will have "the

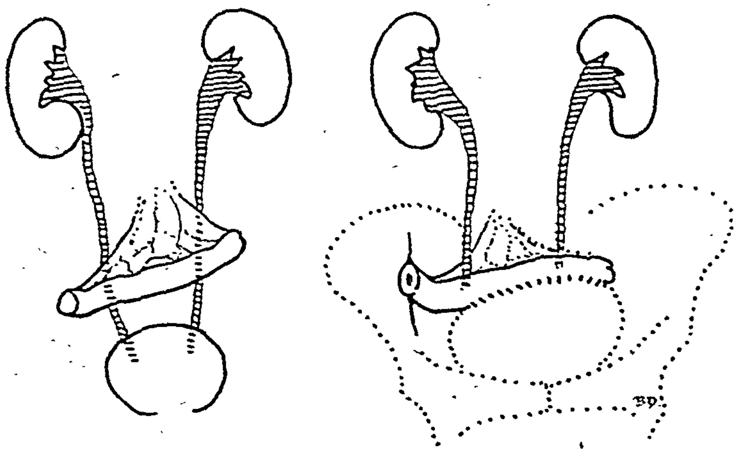

Fig. 5—Implantation of both ureters into isolated ileal segment (case 4).

on the right side. The patient is now well and his blood-urea is 36 mg. per 100 ml.

DISCUSSION

We have treated four patients by this method. In case 1 pyelitis had developed after an isolated segment of ileum was used as a conduit between the ureters and the colon. Once the distal end of the ileum was separated from the colon and drained externally the pyelitis quickly cleared, and the patient has remained well. We feel this can be accepted as positive proof that the colon is the exciting cause of the infection. In this case the external ileostomy provided drainage good enough to allow the infection to clear. So far there have been no recurrent attacks.

In case 2 a solitary left-sided hydronephrosis with gross hydro-ureter followed removal of the other kidney for tuberculosis. It is generally agreed that the transplanting of a grossly dilated ureter into the large bowel is unsatisfactory. If one of the tunnel methods is used, the technical difficulties of getting the whole of the cut end of the ureter into the bowel are almost insurmountable. If an end-to-side anastomosis after the Nesbit operation is done the operation is less difficult, but the chance of an ascending infection is very high. In the present case the ureter was dilated to about 1 in. in diameter, and from earlier notes we found that a hydro-ureter had been present for at least five years. A direct end-to-end anastomosis between the cut end of the ureter and the proximal end of the isolated segment of bowel was the method adopted in this case (fig. 2). It seems that this method of dealing with hydro-ureter and hydronephrosis of the solitary kidney in tuberculosis offers better prospects than any method of implantation into the large bowel. There is certainly less risk of infection, and even when only a small segment of ureter remains above ureteric strictures the method can still be used.

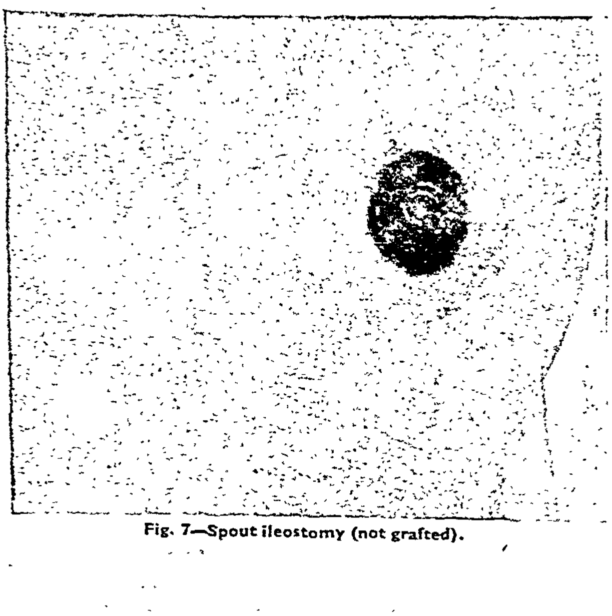

Fig. 7—Spout ileostomy (not grafted).

In cases 3 and 4 transplantation was done for bladder growths.

Preoperative preparation has been with succinyl sulphathiazole and streptomycin by mouth. In all the cases a segment of lower ileum was used and the bowel continuity was restored by end-to-end anastomosis (fig. 1). The length of the isolated segment was estimated by previously applying it along the path in which it would finally lie.

The method of implanting the ureter into the bowel can be either of the mucosa-to-mucosa type, especially if the ureter is slightly dilated, or, as in case 4, a tunnel procedure. Since the risk of reflux is very small a valve is not needed, and the formal anastomosis is probably the better since it is very unlikely to lead to stricture and allows immediate free drainage.

The management of the isolated loop in the peritoneal cavity has varied. In some instances it has been allowed to lie free, but in the later cases it has been closely sutured to the pelvic brim and the iliac fossa on the side on which the ileostomy was to be made (fig. 5). This method has worked satisfactorily and has left no foramina through which gut might herniate. Some of the terminal ileostomies have been made with a small mucosal spout (fig. 7) and others have had a spout covered with skin. It is advisable to have the covered spout about 2 in. long, with its upper surface covered by full-thickness skin with the immediate split-skin graft applied to the under surface. If this technique is adopted the inevitable slight contraction of the graft tends to make the spout turn downwards and fit nicely into the urinal (Wells 1952). These patients have remained dry and comfortable with a close-fitting ileostomy bag (fig. 8). With the flush ileostomies an adhesive bag has been used.

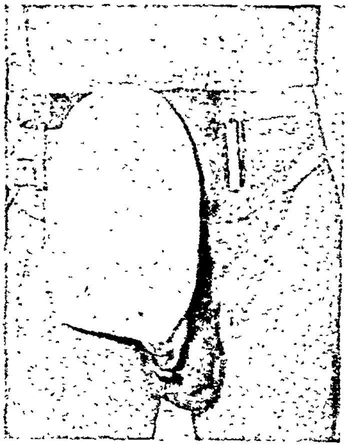

Fig. 8—Ileostomy bag.

After operation urine has flowed freely in $^1/_2$–1 hour. Urine drips constantly; and every few minutes, with contraction of the intestine, it spurts out.

Technically the operation is not difficult; but, compared with ureterocolic anastomosis, more care is needed to secure hæmostasis when dealing with the implant into the small intestine. Unlike the colon, which is relatively avascular, the small intestine bleeds freely.

Although in cases 3 and 4 the implantation and cystectomy were done in one operation, there is no reason why the cystectomy should not be done later. If this were decided, it would be better to bring out the ileostomy in the right or left iliac fossa.

After the operation no patient has shown clinical evidence of pyelonephritis or of renal destruction; all have intravenous pyelograms similar to the preoperative pictures; none have shown any of the biochemical

THE LANCET

LONDON SATURDAY, JUNE 13, 1953

Cation-exchange Resins

A CATION-EXCHANGE resin is formed by the condensation of many molecules of either carboxylic or sulphonic acids to form a high-molecular-weight polymer This is insoluble in water and has many free valency bonds, about half are linked to water, but the rest are available to combine rather loosely with different cations, including hydrogen When a column of resin charged with one cation, such as sodium, is exposed to a solution of the salt of another cation, such as potassium, the sodium and potassium will "exchange,' leaving the resin charged with potassium, if enough potassium-containing solution has been used to perfuse the resin column If instead of using a large quantity of potassium-salt solution, the sodium-charged resin is merely immersed in a solution of potassium salt, an equilibrium will be attained which will depend on the concentration of potassium in the solution, and on the "affinity" of the resin for the different cations In general, resins have most affinity for divalent cations, such as calcium and magnesium, and, among monovalent cations, for potassium, sodium, ammonium, and hydrogen in that order In-vitro experiments indicate that some resins may combine with 5 m eq of cation per g of resin, but when resins are ingested by patients, their power to combine with cations is of the order of 2 m eq per g of resin[1]

Three years ago we noted that, among other applications of exchange resins to medicine, they could be used to withdraw sodium from the diet, and so to permit a more liberal and varied regimen for patients undergoing salt restriction[2]—an application first suggested by DOCK[3] on the basis of experimental work In 1950 suitable resins were becoming available for medical use in this country, but few accounts of their use had been published This deficiency has now been repaired almost to the point of embarrassment, the metabolic effects of exchange resins have been intensively studied,[1 4 5] the clinical indications have been more closely defined,[6–8] and certain hazards of long-continued administration have become apparent[9] Most of the patients studied have been in cardiac failure with œdema,[10] or have had massive œdema due to primary renal disease[11] The resin has been used in conjunction with a low-salt diet, and earlier balance studies[12] suggested that it simply prevented absorption of sodium from the diet but other work has shown at times a fæcal excretion of sodium greater than the dietary sodium[8] The main action of the resin is however, in preventing absorption of sodium, and actual depletion of body sodium takes place mainly by urinary excretion There is some evidence that such excretion may be enhanced in resin-treated patients, and in some cases which have become resistant to mercurial diuretics, resins may restore excretion of sodium after injection of such a diuretic Most of the resins used are in the hydrogen or ammonium cycle, and so have an acidifying effect, they may thus counteract the alkalosis that arises during prolonged mercurial treatment, which is strictly chloruretic rather than natriuretic, simple correction of alkalosis has been observed to restore the diuretic response to mercurials[13] Thus, summing up the credit side of the therapeutic use of resins, it would seem that they are useful adjuvants to a low-sodium diet, and they may restore the diuretic response to mercurials in patients with alkalosis

On the debit side, the original hydrogen-loaded resins caused buccopharyngeal irritation, but this has been controlled by the use of resins in the ammonium cycle Potassium depletion has been observed after some months of treatment with resins,[9] but this can be prevented by giving part of the resin in the potassium cycle A much more serious danger of long-continued resin treatment, when combined with mercurial diuretics, is the production of the "low-salt' syndrome, first described by SCHROEDER,[14] in which, although œdema persists, the actual circulating plasma becomes depleted of salt, this "central salt depletion' exerts its usual unfavourable effects on cardiac output and renal function Patients with this syndrome may occasionally respond to infusion of hypertonic saline[15] or potassium[16], but generally its onset indicates that biochemical tinkering can no longer delay the progress of cardiac failure From their experience of prolonged treatment with resins of patients with congestive heart-failure, GREENMAN et al[9] suggest that for about six months these provide a relatively safe supplement to the basic therapy, but that thereafter "hyponatræmia, hypopotassæmia, and hypocalcæmia are frequently observed"

A less usual, but much more decisive, application of cation-exchange resins in medicine is for the treatment or prevention of potassium intoxication in patients with anuria or severe oliguria ELKINTON et al[17] showed that resin given in a dose of 50 g. per day in the ammonium cycle lowered the serum-potassium, it was best given orally, but some effect could be obtained by rectal administration Here again, resin treatment is not a substitute for the very effective protein-free and electrolyte-free diet of BULL et al[18], but it is a useful addition to their regime when the serum-potassium increases dangerously changes that are associated so often with ureterocolic anastomosis.

SUMMARY

Each of four patients has had the ureters implanted into an isolated length of ileum, through which urine was brought to the abdominal wall to collect in an ileostomy bag.

In two patients the operation was done in association with total cystectomy for carcinoma of the bladder.

In a third it was done after nephro-uretero-cystectomy for diffuse papillomatosis; and in a fourth it was done for multiple urinary fistulæ following nephrectomy for tuberculosis.

All the patients are happy and well; and except in case 1, in which the technique was faulty, there has been no difficulty in keeping dry and in collecting urine in the ileostomy bag.

No patient has shown evidence of the many complications that are known to follow ureterocolic anastomosis.

This method has given us fresh confidence in approaching the operation of total cystectomy and the other procedures where urinary deviation is necessary.

ADDENDUM

Since this article was submitted for publication the operation has been carried out in five other patients.

We wish to thank Miss Barbara Duckworth for the line drawings and Mr. Wilfred Lee, of the University Central Medical Photographic Department, for the reproduction of the radiographs.

AN ARTIFICIAL BLADDER

THOMAS MOORE
M.D., M.S. Durh., F.R.C.S.

SURGEON, WITHINGTON HOSPITAL, MANCHESTER; HONORARY UROLOGIST, MANCHESTER ROYAL INFIRMARY

BILATERAL cutaneous ureterostomy has been proved by general experience to be very unsatisfactory. The mechanical difficulty of collecting the urine from both sides and keeping the patient dry, and the frequent stenosis of the orifices and attacks of ascending renal infection, render subsequent existence often short and always irksome and unpleasant. When, therefore, the bladder is removed by operation, or put out of action by disease, the orthodox procedure is to transplant both ureters into the sigmoid colon. Such patients can lead normal and comfortable lives and die many years later from unrelated diseases, as did one of my patients from coronary thrombosis fourteen years after total cystectomy for carcinoma of the bladder. In these cases the colon has really been reverted to an early developmental stage of a cloaca containing both fæces and urine. It is surprising, however, how many of these patients learn to know when they are going to pass flatus, urine, or fæces. The use of antibiotics has rendered the old danger of attacks of ascending renal infection much less of a menace than formerly.

Because in some cases of extensive pelvic malignant disease it is necessary to remove the lower bowel in addition to the bladder, the formation of some type of artificial bladder had been contemplated. Much experimental work on this subject has been reported from America (Bisgard 1943, Bisgard and Kerr 1949, Rubin 1948, Bricker 1950). Glaser (1952) in this country has recently reviewed the subject. Very few clinical successes have been reported and, so far as I am aware, none have been reported in this country.

METHODS

The following methods are available:

(1) *With preservation of urethral sphincter control.*—In this method the ureters are transplanted into an isolated loop of sigmoid colon, of which the upper end is closed and the lower end is anastomosed to the urethra or to the bladder neck. The continuity of the colon is, of course, restored. So far as I know, this method has only been practised on animals.

(2) *With preservation of anal sphincter control of rectal artificial bladder and establishment of terminal colostomy.*—Some urologists in this country regularly practise this method with total cystectomy. The sigmoid colon is divided and a terminal colostomy fashioned. The ureters are transplanted into the lower part of the colon, of which the upper end is closed. Those who use this method believe that a terminal colostomy is a small price to pay for a smaller risk of ascending pyelonephritis than after orthodox bilateral uretero-sigmoidostomy.

(3) *Skin stoma only of artificial bladder with no sphincter control.*—Here the ureters are transplanted into an isolated loop of small or large bowel, of which one end is closed and the other brought out on the surface of the abdomen. Such patients, of course, have no control over the urinary discharge and must always wear a bag. By making the superficial end of the bowel project a little distance beyond the skin, and by grafting its surface, a Rutzen bag can be made to fit well and to be far less trouble than might be expected.

(4) *Skin stoma only of artificial bladder with sphincter control of ileocæcal valve.*—In this method the ureters are transplanted into the isolated right colon, the right end of the divided transverse colon is closed, bowel continuity is restored by ileo-transverse colostomy, and the distal end of the divided ileum is brought out on the skin-surface as a terminal ileostomy. *Continence depends on the competence of the ileocæcal valve.* In the case reported below this procedure was very satisfactory, the valve being very competent. However, I believe from experience of cases of large-bowel obstruction that the ileocæcal valve is competent only in about 50% of people. It might be worth while, therefore, to prove the competence of the ileocæcal valve by barium enema in every case in which the formation of an artificial bladder from the right colon is contemplated.

INDICATION

The indication for the operation is an extensive malignant pelvic disease in which any chance of cure entails removal of all the pelvic viscera. Though this extensive operation at present is only done in the advanced and hopeless cases, it is likely that by performing it in borderline cases of carcinoma of the rectum, bladder, or uterus, long-term cures would become more common. Perhaps also in cases of urinary fistulæ following malignant infiltration and radiation therapy the formation of an artificial bladder would render life at least tolerable. Occasionally also when the central nervous control of the bladder and rectum has been destroyed, and the resultant sepsis has reduced the capacity of the bladder to that of a mere thimble, as in the case described below, the formation of an artificial bladder could be the bridge from chronic invalidism to an active and useful life.

CASE-RECORD

Miss A, aged 26, was first seen by me at the urological clinic of the Manchester Royal Infirmary in January, 1950, complaining of frequency and precipitancy of micturition for a month. She could not hold the urine for more than thirty minutes during the day and she had to get up many times at night.

She was referred by Dr. Fergus Ferguson, under whose care she was first admitted to the Manchester Royal Infirmary in December, 1945, having had sudden onset of weakness of

Ureteric Transplantation

In the past few years surgeons have been expressing increasing dissatisfaction with the present operations for transplanting the ureters into the large bowel Last year we drew attention to the electrolyte disturbances which may follow the operation[1] the early reports of Ferris and Odel[2] have been repeatedly confirmed, and the recent survey by the British Association of Urological Surgeons of the late results of ureterocolic anastomosis has revealed that, of the cases suitable for analysis, nearly 80% showed some degree of acidosis following operation[3] Many patients with electrolyte disturbances do not show any overt symptoms or signs, but occasionally very serious or even fatal consequences may arise Even in the absence of obvious sequelæ a chronic state of acidosis cannot be regarded with complacency, especially in young children in whom there may be long-term effects on skeletal growth[4 5] The cause of the electrolyte disturbance is still disputed Whilst reabsorption from the bowel is the most widely accepted explanation, many workers[6 7] contend that renal tubular damage resulting from ascending infection plays an equally important rôle Wilkinson[8] has suggested that the primary defect is excessive loss of potassium from the bowel, owing to increased colonic secretion in response to the presence of excessive fluid In addition to the electrolyte disturbances, many other complications may follow the operation Last year's survey[3] showed that complications occurred in 41 4% of the 1673 cases reviewed, 12 6% were the complications of any major operation, whilst the remainder were particularly related to this type of operation and included such conditions as urinary fistula and pyelonephritis The over-all postoperative mortality in the 1673 patients was 21 1%, but, excluding operations for carcinoma, the mortality was 11 5% The mortality figures were not significantly affected by the particular technique of anastomosis, although it was thought that the newer methods of direct anastomosis[9 10] showed promise of being free from many of the defects of the earlier procedures of Coffey[11] and Stiles[12]

With so many hazards it is not surprising that surgeons have been exploring other methods of diverting the urinary stream from the bladder Direct cutaneous ureterostomy is dangerous and unpleasant, making life a burden for the patient Construction of an artificial bladder from a segment of the bowel is, in theory, an attractive solution, but it presents many technical difficulties The earliest experiment on the formation of an artificial bladder was that of Tizzoni and Foggi[13] in 1888, and the operation was first performed on man by Verhoogen[14] in 1908, using a segment of ileum as a bladder and draining it through an appendicostomy The patient died shortly afterwards Other attempts have since been made, but with little success With the increasing scope o cancer surgery, operations for pelvic evisceration hav become increasingly common The "wet colostom which is produced when ureteric transplantation i combined with a colostomy following excision of th lower bowel and the bladder is difficult to manag with comfort, and Bricker[15] therefore revived a early operation and did a ureteric transplant int an isolated loop of ileum, which drained through a ileostomy, together with a separate "dry" colostom He found that patients managed better with tw separate artificial orifices than with a combined one they remained in good health, and up to four year after operation there was no evidence of hydro nephrosis Glaser[16] has recently reviewed the subjec of the artificial bladder and described two main group of procedures By one urethral function is preserved a length of bowel being substituted for the bladde and anastomosed to the ureters above and to th urethra below This operation has been done only o animals[17 18], it is technically difficult, and th indications for it would be very few The other grou or procedures involve substituting for the bladder a length of bowel draining through a skin stoma Th artificial bladder could be fashioned from the ileum from the ileocæcal region, or from a portion of colo alone The indications for this operation would b mainly extensive pelvic cancer or, occasionally intractable vesicovaginal fistula The advantage claimed for the separation of the urinary and fæca streams are that the danger of ascending infection i diminished, the area of mucosa exposed to urine i very much reduced and therefore electrolyte reabsorp tion will be lessened, and the pressure built up insid the artificial bladder will be much less than that which develops in the colon, especially during defæca tion, and so there will be much less risk of regurgitation up the ureters As Annis[19] points out, the indications for establishing a substitute for a ureter alone ar very few, but occasionally it may be possible to preserve a fairly healthy kidney by excising a diseased ureter and replacing it with a length of bowel Davids and Lesnick[20] report successful experimental ureteric substitution in dogs, and suggest that this technique may prove useful in conditions such as penetrating injuries of the ureter, surgical injuries, ureteric tumours, either primary or due to extension from other organs, and ureteric stenosis following healing of a tuberculous ureteritis

This week we publish four papers dealing with the application of these techniques to man Dr Foret and Dr Heuschen report a case in which both ureters were partly replaced by a single isolated loop of ileum Their technique differed from the experimental ones of Annis and Davids and Lesnick in that the base of the intestinal loop was anastomosed to the bladder apparently leaving a free communica tion between the two ureters Their patient survived operation and was in normal health a year later The other three papers all deal with the construction of an artificial bladder Mr Annis and his colleagues did the operation in 9 cases as an alternative to ureteric transplantation The ureters were anastomosed to an

the legs and disturbance of bladder function. She was then found to have transverse myelitis at the level of D10, and she was in hospital and a convalescent home until November, 1946. On discharge she had bilateral spastic paraparesis and pes cavus but could walk fairly well with a stick, and, though normal bladder sensation was absent, she had sufficient awareness of the desire to void to be socially normal and to carry on her occupation as a cashier. She was kept under regular observation by the neurological department of the Manchester Royal Infirmary and seen at short intervals. The improvement in her condition was maintained. During 1947 she had trophic ulceration of both feet, but this healed with simple treatment. In 1948 she had intermittent cramps in the legs and for some time received weekly injections of curarine, with considerable improvement. In December, 1948, she underwent an operation for lengthening the right tendo Achillis. After this she continued work without interruption until January, 1950, when she was readmitted under Dr. Fergus Ferguson because of great deterioration in her urinary condition.

Investigations

On examination I found her in good general condition, with clean and moist tongue and no obvious abnormality of the alimentary, respiratory, cardiovascular, or urinary systems.

Her urine was normal on microscopy and on culture. Her blood-urea level was 40 mg. per 100 ml., and urea clearance was 76% of average normal. On cystometrography the pressure rose to 50 cm. of water with less than 1 oz. of fluid in the bladder. The fluid then began to leak along the side of the catheter. Cystoscopy showed a small bladder containing less than 2 oz. of urine. The mucosa showed diffuse areas of erythema. Both ureteric orifices were normal. No trabeculation was seen. There was no relaxation of the bladder neck. The external urethral sphincter was lax, and the patient had no urethral or bladder sensation. During the cystoscopy the bladder capacity could be increased to 8 oz. by hydrostatic pressure. Ordinary radiography and intravenous urography showed good function of both kidneys but considerable ureteric, pelvic, and caliceal dilatation. The cystogram showed that the bladder was of very small capacity (fig. 1).

It was decided to test the capacity of the rectum to act as an artificial bladder, and many tests were made. The rectal sphincter had fair tone, but the anal canal had no sensation. On many occasions, about 10 oz. of fluid was instilled into the rectum, but the patient had no power to hold it at all. In an attempt to keep the patient dry an inlying urethral catheter was used for several weeks, but urine often leaked alongside it. The patient was eventually transferred to the Withington Hospital under my care on Sept. 7, 1950, when further investigations were made. A blood-count showed 4,630,000 red cells per c.mm., Hb 81%, and white cells 5000 per c.mm. The urine contained a moderate number of red cells and white cells, and on culture gave *Bact. coli*. The blood-urea level was 44 mg. per 100 ml. Cystometrography showed a very hypertonic bladder which would hardly hold any fluid without emptying alongside the catheter. There seemed to be complete absence of bladder sensation.

Progress

About this time the patient had a severe attack of ascending pyelonephritis, due to *Bact. coli*, which responded to sulphonamides. Further tests of the rectal continence showed that ureteric transplantation would be of no avail.

Suprapubic cystostomy.—After a consultation with Dr. Ferguson, although it did not seem likely that a suprapubic cystostomy could be of much benefit to the patient, it was decided to give it a trial. The operation was done on Sept. 20, 1950, under general anæsthesia. The patient made good progress and was discharged on Nov. 11, 1950, having been fitted with a Millin suprapubic bag. For a short time she appeared to be much more comfortable but then urethral leakage started again.

Millin sling operation.—On readmission on Dec. 13, 1950, retrograde cystography showed a very tiny bladder with reflux up both ureters. As ureteric transplantation was fraught with the danger of rectal incontinence; and there was the secondary possibility of ascending renal infection, it was decided to try and tighten the urethra. Riches has sometimes done this in cases of neurogenic bladder with a very lax urethra (Riches 1951). On Feb. 26, 1951, I did a Millin sling operation on the urethra through a transverse lower abdominal incision under general anæsthesia. The patient made good progress after this and was discharged on April 4, 1951. She had had no incontinence since the operation, and abdominal exercises had improved the tone of her muscles very much indeed. She went back to work and was fairly comfortable.

Obliteration of urethra.—Readmitted on Oct. 3, 1951, because of further urethral leakage, she pleaded that the urethra should be obliterated. I was not very keen to do this, because it meant that the suprapubic cystostomy would definitely be permanent, and I always lived in the false hope that the nervous disease might recover. However, on Oct. 11, 1951, I exposed the urethra from below under general anæsthesia, ligatured it, and sutured the superficial tissues together over it. The patient was very well afterwards but started to leak again on Nov. 3. Further attempts to obliterate the urethra were made on Nov. 15 and Dec. 6, and again were unsuccessful.

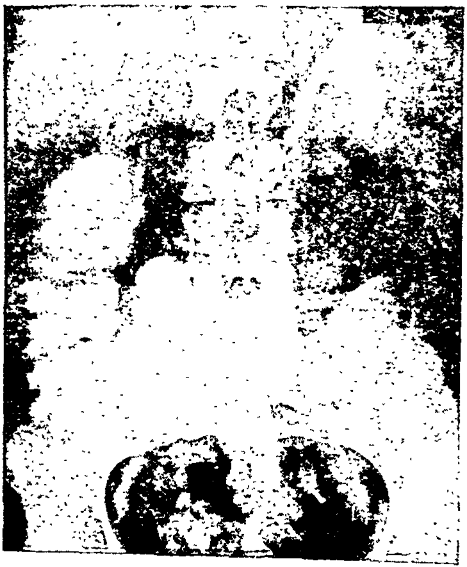

Fig. 2—Intravenous urogram with retrograde cystogram of artificial bladder showing good function of both kidneys. Right kidney has returned nearly to normal; left kidney is still considerably dilated.

isolated loop of ileum. This was brought to the surface as a flush ileostomy, or else a spout was fashioned; in either case it was possible to fit a satisfactory ileostomy bag. All of these cases have been free from trouble up to the time of reporting. In the 1st case a *transplantation operation was done at first, using a* loop of ileum as a bridge between the colon and the ureters. It was hoped by this means to prevent regurgitation from the bowel up the ureter, but, although there was no radiographic evidence of such regurgitation, the patient developed attacks of pyelitis. After the ileal loop was separated and brought to the surface, there were no further attacks. Mr. MOORE had the difficult problem of treating a contracted paralytic bladder in a patient who had had transverse myelitis and who was unable to hold even a small volume of fluid in her rectum. He constructed from the ascending colon an artificial bladder draining through an ileostomy. As the ileocæcal valve was competent his patient was able to hold urine in her bladder for two hours. Her progress was very satisfactory up to the time of reporting five months later. BRICKER[21] failed to produce a continent intra-abdominal urinary pouch and has now abandoned the attempt. He prefers to use a short ileal loop as a conduit rather than a storage receptacle, since this lessens the risk of a stagnant pool of urine becoming infected and also reduces both the area of mucosa available for reabsorption and the length of time that urine is exposed. The last paper, by Dr. WILSON, is a careful study of a single patient who developed a temporary electrolyte disturbance after transplantation of the ureters into an isolated loop of ileum. EISEMAN and BRICKER[22] have studied the absorption of electrolytes from isolated ileal loops before and after implantation of the ureters. Urea and chloride were both absorbed, although the absorption was relatively slow; and they pointed out that, provided the loop is fairly short, the quantities absorbed would not be enough to produce any distinct changes in the serum chemistry. The fact that the changes in Mr. MOORE's patient were only temporary would suggest that some other factor than simple reabsorption of electrolytes was the main cause. Whether this factor was impairment of renal function or, as he suggests, some change in the function of the ileal mucosa cannot be decided with certainty.

As yet few patients have had this type of operation and the period of observation has been too short for proper assessment. HIGGINS[23] found in dogs that when the isolated lower segment of the rectosigmoid was used as an artificial bladder it contracted down after two years so that its capacity was practically nil. So far there have been no reports of late contractions of the artificial bladder in man, but careful follow-up studies will be needed to clarify this point. MITCHELL and VALK[24] declare that "diversion of the urine to the bowel is much too valuable a procedure to be abandoned because of a resulting abnormality in the body chemistry"; but this is only one of the many troubles that may follow ureteric transplantation into the colon, and there is a clear need for further investigation, both clinical and experimental, of alternative procedures.

Annotations

THE DENTISTS AND THE MINISTRY OF HEALTH

THE decline in demand for treatment following the imposition of charges in the National Health Service cannot yet be said to have had a decisive effect upon the recruitment of dental officers to the school dental service, whose staffs were so seriously depleted in the early years of the N.H.S. Though the number of school dentists in England, Wales, and Scotland has risen from the equivalent of 817 full-time officers in January, 1952, to 998, this trend cannot be expected to continue long enough to bring substantial relief to a service nominally responsible for the dental care of $5^1/_2$–6 million children. The ground lost since 1947 has not yet been recovered, and, as the numbers of newly qualified dentists will soon be insufficient to replace those retiring from practice each year, it cannot be hoped that the service will ever have enough members to provide comprehensive dental care for all the children of the country.

An anomalous position has arisen in which, for the first time for several years, many dental practitioners are not fully occupied and would be willing to accept more children as patients in their practices under the N.H.S., while the school dental service remains seriously understaffed and unable to fulfil its responsibilities. The British Dental Association contends that this anomaly could be abolished to the benefit of all parties by a simple administrative procedure by which the school dental service would arrange with practitioners to treat in their surgeries, those children who cannot through pressure of numbers be given treatment in the school clinics. For some months the association has been trying to persuade the Government to accept this suggestion; but the recent publication of its correspondence with the Minister of Health shows that little progress has been made. In a letter dated March 30, 1953, the association refers to the "very large measure of agreement" between the parties on the subject of the dental treatment of children. The two sides agreed that the best method of providing necessary treatment was by means of full-time salaried dental officers in the school dental service, and that their recruitment should proceed as quickly as possible. Meanwhile the service should be supplemented by general practitioners working in local-authority *clinics as part-time officers on a sessional basis*; but for some years to come there would inevitably remain in certain areas a considerable number of children unable to obtain necessary treatment through the school dental service. The association proposed that these children should most appropriately obtain treatment through part IV of the National Health Service Act, 1946, and "that it was highly desirable that the parents of these children should be encouraged to take them for treatment to a practitioner in the general dental service." The Minister of Health's reply of May 2 defines the main point at issue between the parties as the association's suggestion that the dental services of local authorities should take the initiative in referring children for treatment to dentists willing to provide it under the general dental service, and considers this proposal "would have an adverse effect on recruitment and thus could not fail to hinder the development of a service for children." The local dental executive committees were the bodies designed to give this kind of help and advice to the public. The letter records the Minister's appreciation of the way in which dentists are coming forward with offers of help as part-time officers in the school clinics, and considers that this help is largely responsible for the improved staffing of the school service.

The Government evidently think the British Dental Association's scheme would be too costly, and by dividing the treatment of school children between two distinct

The Artificial Bladder

We then decided that the only possible course was to form an artificial bladder. Repeated investigations had confirmed that the bladder was very small and contracted, and the upper urinary tract much dilated, and from time to time the patient had had severe attacks of ascending pyelonephritis.

Operation.—On May 1, 1952, under general anæsthesia, the transverse colon was divided, through a right paramedian incision, near its right end, and its proximal end was closed. The ileum was divided across in its last 6 inches, and an ileo-transverse colostomy was made. The lower end of the ileum was brought out through the middle of the wound. The patient was very ill after this operation, largely owing to the weak abdominal muscles which made respiration difficult, but she gradually improved on careful treatment and got up and about again. We were interested to know how much absorption would take place from the isolated right colon, and many tests were made, 10 oz. of physiological saline solution being run into it and drained off again after two hours. During this time about 40% of the fluid content and 52% of the chloride were absorbed.

The second stage of the operation was performed on July 14, under general anæsthesia, through a transverse lower abdominal incision dividing both rectus muscles. The left ureter was transplanted into the left side of the cæcum, which was mobile and could be brought over to it and sutured to the incision in the parietal peritoneum so that the anastomosis was extraperitoneal. The right ureter was transplanted into the right of the cæcum by a similar method. In both cases direct union by mucosal sutures was made. The appendix was removed. A Foley catheter was left in the cæcum through the terminal ileum.

Postoperatively the patient made very satisfactory progress. A careful check was kept on the blood chemistry, which remained normal throughout. The patient was eventually discharged on Oct. 8, when she was very well, could hold her urine in the artificial bladder for two hours and, by catheterising herself during the day, remain dry and comfortable. During the night a catheter was passed into the cæcum and left there and allowed to drain. This routine was adopted because of the great danger of absorption from the artificial bladder if it was allowed to contain urine all night.

Follow-up.—The patient was last seen on Jan. 21, 1953, when she was very well in herself ("better than she has been for years") and even walking much better. The artificial bladder was no trouble. She was emptying it every two hours during the day and leaving a catheter in all night. She was on a salt-free diet and taking an alkaline mixture by mouth. Her blood-urea level was 24 mg. per 100 ml. Detailed chemical investigations of the blood showed that the content of calcium, sodium, potassium, phosphate, and chloride and the alkaline reserve were normal. Intravenous urography (fig. 2) showed excellent function of both kidneys. Practically all the dilatation of the right ureter, pelvis, and calices had disappeared, but that on the left side, although much better, was still considerable. Since discharge the patient had continued her occupation as a cashier and had lost no time from work.

SUMMARY

Infection and contraction of the bladder following transverse myelitis, caused total urinary incontinence.

This was treated by the formation of an artificial bladder from the right colon. The result was excellent, and the patient has returned to her normal occupation.

The possible uses of an artificial bladder in surgical treatment are briefly reviewed.

That a successful result was eventually obtained was in a large part due to the devoted attention of Sister Townes and her nurses at the Withington Hospital, the many anæsthetists who from time to time administered to the patient, my successive registrars and house-surgeons, and not least to the patient's own great moral courage and unshakable confidence.

HYPERCHLORÆMIC ACIDOSIS FOLLOWING IMPLANTATION OF THE URETERS INTO AN ISOLATED LOOP OF ILEUM

A. O. WILSON
B.Sc., M.B. Edin.
REGISTRAR, DEPARTMENT OF SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

ELECTROLYTE imbalance in surgical patients has been extensively studied during the past decade, and particular attention has been directed recently to the problems of electrolyte imbalance following implantation of the ureters into the sigmoid colon. So far as is known hyperchloræmic acidosis following ureteric implantation into an isolated loop of ileum has been described in only one patient (Bricker 1952, Eiseman and Bricker 1952). Substitution of a short isolated loop of terminal ileum for the bladder, with end-to-end restoration of ileal continuity, first reported by Bricker (1950), does not yet seem to have been extensively practised.

CASE-RECORD

A 74-year-old man in good general condition was admitted to hospital on Jan. 2, 1952, with a history of loss of weight and vague abdominal pain during the preceding month. Rectal examination showed a moderately enlarged prostate. Occult blood was present in the stool, and a preliminary laparotomy on Jan. 29 showed a carcinoma of the recto-sigmoid. A left iliac colostomy was made. Because the tumour had invaded the bladder, it was necessary at the operation on March 3 to carry out pelvic evisceration with transplantation of the ureters into an isolated 6-inch loop of *terminal ileum.*

Preoperative excretion pyelograms showed poor concentration of the dye on both sides at ten and twenty minutes. The preoperative blood-urea level was 24 mg. per 100 ml.

Postoperative Progress

During the first two weeks convalescence was satisfactory, apart from a mild chest complication. The urine output on the day of operation was 300 ml., on the next day 635 ml., and thereafter averaged 1520 ml. per day during the remainder of the period of investigation. On March 18, *fifteen* days after operation, the patient was obviously unwell and was very drowsy, but no gross abnormality could be found on clinical examination. The blood chemistry was:

Urea	74	mg. per *100 ml.*
Sodium	134·5	m.eq. per litre
Potassium	5·0	m.eq. ,, ,,
CO_2-combining-power	12·5	m.eq. ,, ,,
Chloride	107·5	m.eq. ,, ,,

To correct the acidosis, sodium citrate was given by mouth (2 g. t.d.s.) *from* March 19 for thirteen days. On March 20 the blood chemistry was:

Urea	84	mg. per 100 ml.
CO_2-combining-power	12·5	m.eq. per litre
Chloride	99·1	m.eq. ,, ,,

To determine whether some obstruction had developed at the uretero-ileal *anastomoses, indigo-carmine* (5 *ml.*) was injected intravenously, and appeared at the "ileostomy" *fourteen minutes after injection.*

By March 28 his general condition had improved greatly: he had become completely alert and was feeling very well. The acidosis had been largely corrected, and the blood chemistry was:

Urea	40	mg. per 100 ml.
Sodium	142 0	m.eq. per litre
CO_2-combining-power	20·0	m.eq. ,, ,,
Chloride	97·7	m.eq. ,, ,,

On April 4 blood examination showed:

Urea	29	mg. per 100 ml.
Sodium	148·0	m.eq. per litre
Potassium	4·6	m.eq. ,, ,,
CO_2-combining-power	25·3	m.eq. ,, ,,
Chloride	101·7	m.eq. ,, ,,

A second injection of indigo-carmine on April 5 was *followed* by the appearance of the dye at the "ileostomy" in twelve minutes. An excretion pyelogram on April 7 showed good excretion on both sides at five minutes.

Since discharge from hospital on April 9 he has remained well. No sodium citrate was taken *after* April 9. On Oct. 8 a further excretion pyelogram was considered to be *normal.*

services—the National Health Service and the local-authority school service—would threaten the future development of the latter It would certainly be hard to predict the consequences of having part of the work paid for by fees per item of service while the rest was performed by dentists receiving a salary which is at present below the average for N H S general dental practitioners But the essential argument against the association's plan is surely that it offers a short term palliative rather than a solution to the problem It seems a pity that some means cannot be found to make greater use of the help offered by the dental profession, but the million half hour appointments which the association believes that private practitioners would set aside each year for child patients could affect only about 250,000 additional children Only so many would be able to receive reasonably full dental care, and the vast majority of the young would still only be able to obtain emergency treatment for relief of pain On the other hand, the Minister of Health would be rash to assume that prolongation of the present depressed state of general dental practice is going to abolish the staffing difficulties of the public services, or that it could be the basis of a sound school service

Discussions will remain unrealistic until both sides recognise that the dental profession is too small to fulfil all its tasks, and will soon be growing smaller The present slacking in demand for adult treatment does not indicate that the community has suddenly ceased to need dental care it is simply a measure of the public's indifference to, and ignorance of, the importance of dental health It would be unfair to consider either the Minister of Health or the British Dental Association guilty of complacency about this, though their exchange of letters does not suggest that either has given much thought to its significance

CORTISONE IN BELL'S PALSY

MANY different pathological processes can give rise to paralysis of the facial muscles, but in most cases the cause is an apparently intrinsic peripheral lesion of the facial nerve It is to this type that the name Bell's palsy has been given, and, as Kettel[1] points out, this title covers all cases of facial paralysis in which no clear local cause is evident Speculation about the origin of this condition has resolved itself into two main channels Kettel[1] and Hall,[2] among others, believe that the prime cause is local ischæmia, whilst Morris[3] holds that it is an inflammatory process in the nerve and its sheath Most workers agree, however, that the nerve is compressed within the fallopian canal, and that this compression contributes to the impairment of neural function It was to alleviate the long term effects of such compression that Ballance and Duel[4] devised their operation of decompression of the nerve, their technique has been employed by the protagonists of both schools, each school very reasonably supporting this practice by its own theory of the lesion Most cases of Bell's palsy recover spontaneously, usually recovery begins after about three or four weeks, and usually this recovery is complete Those who consider doing decompressive operations are guided both by the persistence of the paralysis beyond the first four weeks and by the absence of response to faradism The operation tends, therefore, to be done some time between the sixth and tenth weeks

This latent period—the natural consequence of therapeutic prudence—is undesirable if the enduring and disfiguring paralysis seen in certain cases is really due to the compressive effect of inflammatory œdema A report by Rothendler[5] is therefore of special interest both for its therapeutic and for its ætiological implications Believing that the palsy is due to a non-specific acute inflammatory reaction, Rothendler decided to try the effects of cortisone He treated 5 cases within five days of onset, 1 at nine days, and another at ten days The cortisone dosage varied, but the course amounted to about 3 g given orally or intramuscularly over a twelve day period In 6 of the cases recovery began in the first week and was complete at the end of the second In the 7th case, in which the treatment was unsuccessful the paralysis was very severe and had already been present for ten days when treatment began In the first 6 cases the rapid and complete recovery was clearly not spontaneous Rothendler expresses the view that cortisone relieves the acute œdema and inflammatory reaction in the nerve and its sheath, and indeed the success of this treatment constitutes prima-facie support for the inflammatory hypothesis of causation It may well be that the old name "rheumatic facial paralysis" deserves more respect than has been accorded to it by modern authorities

Cortisone is still difficult to obtain in this country, and its administration is associated with certain hazards Nevertheless, the striking benefit from so short a course of treatment, and the implied avoidance of the danger of permanent disfiguration, certainly justifies an extended trial of this drug in Bell's palsy—always provided, of course, that it is given in the first few days after the onset of the disease

CONTINUOUS OR DISCONTINUOUS PENICILLIN

WE have lately drawn attention to the desirability of basing the dosage of antibiotics on the in-vitro sensitivity of the infecting organisms[6] The work of Gould et al[7] has shown that the logical interpretation of laboratory tests can lead to successful treatment with doses very much less than the "standard" ones, at any rate in urinary tract infections Undesirable side effects are diminished or eliminated by this means, and the danger of producing resistant strains of bacteria seems to be much less than might have been expected Gould and his colleagues gave the drugs at 6 hourly intervals, and a report by Eagle et al[8] now suggests that attention to the spacing of doses may still further increase the efficiency of treatment They investigated the relation between the dosage, the interval between injections, and the therapeutic efficiency in streptococcal infections of mice

Chain and Duthie[9] demonstrated that penicillin exerted its greatest bactericidal action on organisms in the logarithmic phase of growth This indicated that the efficiency of therapy might be increased if the interval between two injections was such that dormant organisms had begun to multiply by the time of the second injection Eagle et al, however, conclude that the greatest efficiency is achieved when the penicillin concentration at the site of the infection is continuously maintained at the level which exerts the maximal bactericidal action in vitro They found that a penicillin free interval between injections prolonged the total duration of treatment necessary for cure They injected large numbers of mice intramuscularly with a highly virulent strain of group A streptococcus, and penicillin was then given to these mice according to a number of different treatment schedules The intervals between injections were $^{3}/_{4}$, $1^{1}/_{2}$, 3, 6, 12 and 24 hours and the number of injections varied from one to sixteen On each schedule mice

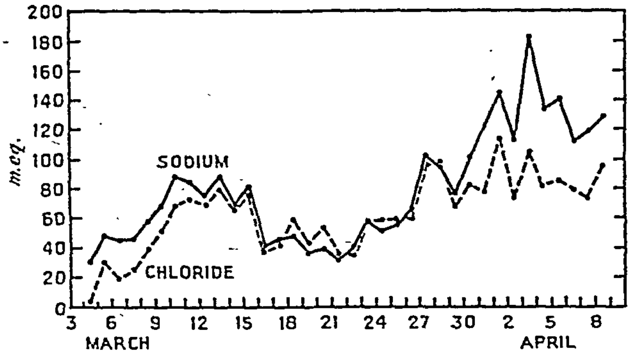

Fig. 1—Daily output of sodium and chloride during the period of study.

SPECIAL STUDIES

Methods.—Collection of urine began on the day after operation. The urine was collected into a Rutzen bag applied to the "ileostomy" and determinations were made on twenty-four-hour samples from 8 A.M. to 8 A.M.

Sodium was measured by an internal standard flame photometer, chloride by Sendroy's method (modified by van Slyke and Hiller 1947), and urea by the hypobromite method.

Sodium citrate administration began on March 19, (2 g. t.d.s.). During the last eight days of the period of study the amount was varied, being increased to 3 g. t.d.s. for four days, and then reduced to 1 g. t.d.s. for the last four days.

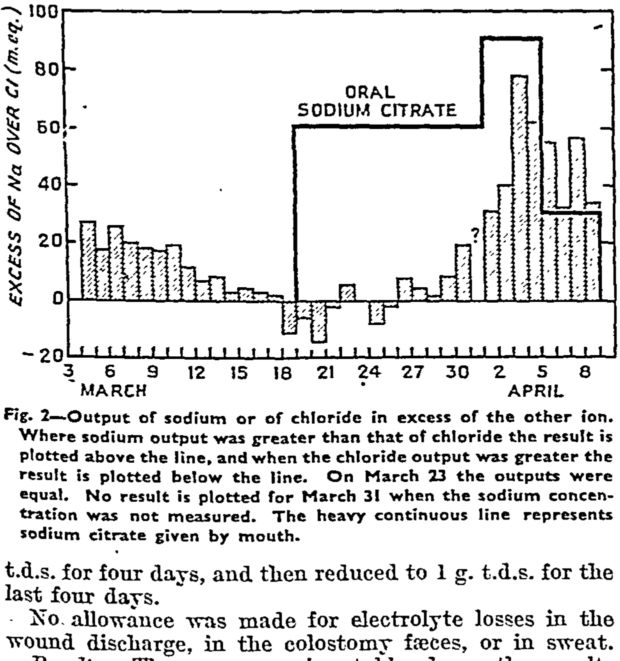

Fig. 2—Output of sodium or of chloride in excess of the other ion. Where sodium output was greater than that of chloride the result is plotted above the line, and when the chloride output was greater the result is plotted below the line. On March 23 the outputs were equal. No result is plotted for March 31 when the sodium concentration was not measured. The heavy continuous line represents sodium citrate given by mouth.

No allowance was made for electrolyte losses in the wound discharge, in the colostomy fæces, or in sweat.

Results.—The accompanying table shows the results of the urine analysis. Up to the fourteenth day after the implantation operation the patient made satisfactory progress, but next day he was in a state of moderately severe acidosis, the CO_2-combining-power of the plasma was 12·5 m.eq. per litre and the chloride concentration was just above the upper limit of normal. By the same date the blood-urea level had risen from a preoperative figure of 24 mg. per 100 ml. to 74 mg. Treatment with sodium citrate began on the sixteenth postoperative day, and was followed first by a fall in the chloride concentration and later by a correction of the low CO_2-combining-power. The blood chemistry was normal on the thirty-second day after operation.

Except on the first two days after operation, the urine volume was adequate, averaging 1520 ml. a day. The urea concentration in the urine showed little variation from day to day, but tended to fall from March 26 onwards. Sodium and chloride excretion ran more or less parallel during the first four weeks after operation (fig. 1). The outputs of each were low at first, but rose during the first week after operation, and remained fairly constant for six days. There was an appreciable fall in the daily outputs of sodium and chloride in the third week after operation, but this was followed by a rise in the amounts excreted during the fourth week.

At first the excretion of sodium exceeded that of chloride, although there was a gradual decrease in the amount by which the sodium excretion exceeded chloride excretion during the first two weeks after operation (fig. 2). During the third and fourth postoperative weeks the sodium output bore an inconstant relationship to the chloride output, while in the fifth week the excretion of sodium gradually increased until it exceeded that of chloride by an amount which approximated closely to the amount of sodium administered as sodium citrate.

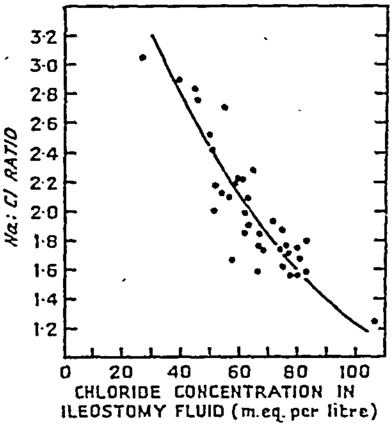

Fig. 3—The relation between the Na : Cl ratio and the chloride concentration in 37 samples of normal ileostomy fluid.

DISCUSSION

The interpretation of the blood and urine changes in this case is difficult. The five weeks of this study may arbitrarily be divided into three periods, the first lasting for eleven days from the day of operation until March 14, the second for fourteen days from March 14 to March 28, and the third from March 28 onwards.

In the first postoperative period of eleven days 180 m.eq. of sodium was excreted in the urine in excess of chloride. Assuming that in the diet taken by the patient during this period the Na/Cl ratio was approximately 1, it is surprising that the urinary loss of sodium was so much in excess of chloride, especially when there was a considerable serous discharge from the pelvic wound, presumably with a sodium concentration greater than its chloride concentration. Extrarenal loss of sodium in excess of chloride is usually associated with the excretion of a urine in which the Na/Cl ratio is considerably less than 1 (Denton et al. 1951, Wilson 1952). "Post-renal" modification of the urine by the ileal mucosa may have counteracted any renal response which there may have been to the developing sodium depletion and acidosis.

In an attempt to elucidate the problem of the development of a state of hyperchloræmic acidosis in this patient, a parallel study was made of the sodium and chloride content of normal ileostomy fluid. The sodium concentration of this fluid is greater than that of chloride (fig. 3).

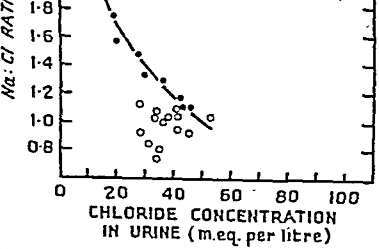

Fig. 4—The Na : Cl ratio in the urine of the present case has been plotted against the chloride concentration. Each dot or circle represents one day

were injected at each of seven dosage levels (0 05, 0 2, 0 8, 3 2 12 5 50, and 200 mg per kg body-weight) The 50% survival rate of each group was then determined The full mathematical analysis of the series was complicated, but the authors selected for detailed comment those aspects directly connected with the problem under investigation For example, six to eight injections, each of 3 2 mg of penicillin per kg body-weight, given at intervals of $^{3}/_{4}$ hour, were needed for a 50% survival in one group of mice If injections of the same dose were given three hourly, only two or three injections gave the same survival-rate Increasing the intervals to 12 hours, however, necessitated three or four injections Comparable results were found with all other doses investigated It is clear that if the intervals were too short, penicillin was still present in effective concentration at the time of each injection, so that the full benefit of the preceding injection was lost If the intervals between injections were too long, then the organism multiplied and longer treatment was necessary The total treatment time required for mice injected every $^{3}/_{4}$ hour was $4^{1}/_{2}$ to 6 hours with 3-hourly injections it was 6 to 9 hours, and with 12 hourly injections 36 to 48 hours The interval between injections also had a pronounced effect on the total dose of penicillin required to effect a cure For example, when four injections were given at intervals of $^{3}/_{4}$ hour, a total dose of 68 mg per kg was needed When the four injections were given at 3 hourly intervals, however, the total dose needed was only 3 mg per kg, while for four 12-hourly injections the total dose for cure was 7 6 mg per kg

The streptococcus used by Eagle et al was killed at a maximum rate in vitro by 0 024 µg of penicillin per ml Approximately half of the penicillin in the blood-stream is bound to serum-protein, so that a serum concentration of about 0 05 µg per ml would be needed to provide maximum bactericidal action in tissue fluids Eagle and his colleagues have determined the total time for which the serum-penicillin level was at or above this critical level in groups of mice treated by various schedules until they were cured They call this the " aggregate penicillin time " The number of injections varied from one to twelve, and the intervals between injections from $^{3}/_{4}$ hour to 12 hours, but the aggregate penicillin time remained remarkably constant at about 4 hours throughout the series Increasing the interval between injections to 24 hours, however, caused a sharp rise in the penicillin time necessary for cure, apparently because of bacterial multiplication between injections These results indicate that the efficacy of penicillin treatment is determined primarily by the total time for which the drug remains at effective levels at the site of infection, provided that the interval between injections is not long enough to allow bacterial multiplication

It is a far cry from mice to men, but in this instance the same factors are likely to govern the response of both species The work of Eagle et al suggests that penicillin should be given to man in a way that ensures that the concentration at the site of infection remains continuously in excess of that necessary to kill the infecting organism in vitro The exact timing of the injections would depend upon the preparation and dose of penicillin used, but the most economical régime, and the one which would produce the most rapid cure, would be that in which each injection was given when the penicillin concentration at the site of infection had fallen to the in-vitro bactericidal concentration for the organism concerned Knowledge of the concentrations of antibiotics that can be attained in the tissues is at present scanty, but advances in this direction, combined with rational interpretation of bacterial sensitivity tests, should clearly lead to a reduction in the massive doses of antibiotics at present given, and therefore to less side-effects and unnecessary expense

TREATMENT OF COUGH

It is not always easy to decide when to interfere with a cough—particularly a postoperative one Even when the decision to treat it has been made, the choice of remedies is enormous, though the really effective drugs are few A conference [1] at Cornell University has lately debated these questions

The majority of the drugs which are said to stimulate the respiratory secretions are emetic when given in large enough doses, but it is extremely doubtful whether they have any real effect in the doses usually given Boyd et al [2–5] have shown that in lightly anæsthetised cats ammonium chloride and carbonate, ipecacuanha, tinct camph co, potassium iodide, creosote, and several of the essential oils will all increase the volume of fluid secreted by the respiratory tract In man, however, there is no such evidence Both Alstead [6] and Howell,[7] who have made long and painstaking studies of the volume of the sputum secreted by chronic bronchitics, failed to show that it was influenced at all by any of a large number of expectorants used in conventional doses But Herxheimer and McAllen [8] have recently suggested a method of using potassium iodide intermittently in doses of gr 15–25 which they claim does produce a real increase in respiratory secretion Probably one of the best expectorants is a hot drink, many a chronic bronchitic and sanatorium patient will testify to the value of his early morning cup of tea as a loosener of phlegm This probably explains the popularity of the celebrated hot-water mixture (mist sod chlor *N F*)

Of the opiates and their derivatives and the few other drugs, such as methadone, which depress the cough reflex, linctus diamorphinæ is incomparably the most effective, but the danger of addiction means that it must be kept strictly in reserve and used only when all safer drugs have failed One speaker at the Cornell conference advocated the wider use of small doses of morphine, but, for the same reason, few would agree with him The main discussion concerned the dosage of codeine The preparations normally used in this country contain quite small doses For example, the ordinary linctus codeinæ *N.F* contains gr $^{1}/_{8}$ to the drachm and the strong linctus gr $^{1}/_{4}$ Many people, including Alstead, have recommended larger doses—e g, gr 1 four-hourly On the other hand, Muschenheim, at the Cornell conference, made a plea for smaller doses at shorter intervals He cited an experiment carried out before the war in an American sanatorium by Davenport,[9] who found that out of 475 patients with troublesome cough only 21 required more than gr $^{1}/_{6}$ of codeine to control it—only one-third of the traditional dose formerly given in this institution But Hillis [10] found no evidence that the action of codeine, even in large doses of up to gr 3, was any greater than could be explained by the factor of suggestion In experimentally produced cough in man he was impressed by the importance of the psychological factor in contributing to the success of various drugs—which may well account for the divergent views on the optimum dosage of codeine

The dry hacking cough of tracheitis and acute bronchitis is helped by warm moist air, and the Americans favour continuous treatment with a steam kettle rather than the intermittent treatment with jug and towel, which is perhaps more popular in this country The wheezing cough is helped by antispasmodics, and one

The fact that the Na/Cl ratio varies with the chloride *concentration suggests that the rates of absorption* by the bowel of sodium and chloride are neither equal nor proportional to the concentrations of the two ions. At any particular chloride concentration the sodium concentration is, within limits, a certain function of the chloride concentration. The curve in fig. 3 bears a striking resemblance to that in fig. 4, which was obtained by plotting the Na/Cl ratio against the chloride content of the urine during the first postoperative period in this patient with ureteric transplantation into the ileum. It is therefore suggested that during the first eleven-day period the mucosa of the ileal loop was functioning more or less normally, attempting to produce a fluid in which the sodium and chloride concentrations bore some predetermined relation to each other. During the second period of fourteen days this early correlation between sodium and chloride concentration disappeared (fig. 4).

The patient had become clearly unwell about the middle of the second period, by which time a severe acidosis was present. The urine Na/Cl ratio fluctuated appreciably during this second period, and the disappearance of the previous relationship between sodium and chloride output suggests that the activity of the ileal mucosa had now become modified. Also, during this fourteen-day period the excretion of sodium and of chloride decreased. Such a decrease might be anticipated if, in the presence of a more or less constant intake and normal renal function, a deficit of these ions had developed. A state of sodium deficiency in fact developed during the first period of eleven days, to which the excess of urinary sodium over chloride contributed. Furthermore, during this first period the daily output of sodium and of chloride had risen rapidly, more rapidly in fact than would be expected after a major operation (Wilkinson et al. 1949). Absence of the usual postoperative period of chloride retention in this case may have been associated with some degree of chloride deficit. The fact that during the second period of fourteen days the daily outputs of both sodium and chloride fell, sodium more than chloride, is further evidence that the initial activity of the ileal mucosa had become modified, and that normal renal responses to states of sodium and chloride deficit were becoming manifest.

POSTOPERATIVE CHANGES IN URINE

During the second period treatment with sodium citrate was started, and between March 19 and March 28 550 m.eq. of sodium was given. Despite this, the excretion of sodium in the urine was still less than, or only just in excess of, that of chloride. It seems probable therefore that the sodium deficit had only just been made good by the end of the second period.

Only during the last six days of the study did the output of sodium in the urine exceed that of chloride by approximately that amount of sodium given as citrate. This might be expected if renal function, with regard to sodium deficit or excess, were normal, and if the urine passed at the "ileostomy" was not modified by the ileal mucosa.

In spite of the excretion of apparently adequate amounts of urea (see table) the blood-urea level rose from 24 mg. per 100 ml. preoperatively to 84 mg. on March 20. Eiseman and Bricker (1952) investigated the absorption of urea from an ileal loop isolated from both urinary and fæcal streams, and they showed that after the urine had been in the ileum for about two hours there was no further appreciable fall in the concentration of non-protein nitrogen, which was between 500 and 700 mg. per 100 ml. This concentration of non-protein nitrogen is comparable to the urea concentration observed in the present case. The mechanism of the fall in blood urea between March 20 and April 4 is obscure, for it is unlikely that the permeability of the ileal mucosa decreased with a reduction in activity of the mucosa. It is possible, however, that the uptake of urea from the ileum is an active process and is related to the general activity of the mucosa.

There is another possible explanation of some of the observations made in this case. Before operation the intravenous pyelogram showed poor renal concentration of the contrast medium although the blood-urea level was normal. The prostate was moderately enlarged, but the patient gave no history of chronic urinary obstruction. Unfortunately the complete blood chemistry was not investigated before operation. It has been pointed out that hyperchloræmic acidosis may develop in cases of chronic prostatic obstruction, the blood chemistry returning to normal after relief of the obstruction (Shackman 1952). A restoration of certain aspects of renal function has also been observed by Lich (1942) and Hughes (1946). It could be argued that in the present case there was some reversible impairment of renal function due to mild prostatic obstruction, which was relieved by transplantation of the ureters into the ileal loop, or that mild obstruction developed following operation. The first possibility is supported by the postoperative improvement of the intravenous pyelogram, but it does not explain the development of acidosis *after relief of the obstruction.* The speed with which the indigo-carmine appeared at the "ileostomy" is against the second possibility. The fact that the patient remained well after discharge from hospital, even without oral sodium citrate, supports the supposition that the mechanism responsible for the acidosis had then ceased to operate.

SUMMARY

A man of 74, with carcinoma of the pelvic colon, had hyperchloræmic acidosis following pelvic evisceration and transplantation of both ureters into an isolated loop of terminal ileum.

The function of the ileal mucosa in the early postoperative period may have contributed to the sodium deficiency which developed, and it may have counteracted the normal renal responses to this deficiency. The activity of the mucosa subsequently changed, with *reduction in, and finally cessation of,* "post-renal" modification of the urine by the bowel.

References at foot of next column

of the Cornell speakers emphasised the value of intravenous aminophylline in the treatment of cough associated with an asthmatic attack The productive coughs of bronchiectasis and chronic bronchitis can be greatly assisted by intelligent postural drainage The patient will soon learn that his comfort can be much increased by clearing the chest at certain strategic times—for example, before meals, before bed and before the day's work The troublesome exacerbations of infection, which are a feature of chronic bronchitis, may be shortened by continuous postural drainage, such as is commonly used in the treatment of lung abscess Unfortunately this method is no good for those patients whose condition has deteriorated to the point of heart-failure, it is really they who need it most, but they must be nursed sitting up Of course, a stubborn nocturnal cough may be an early sign of cardiac failure from other causes, and for these patients an extra pillow, digitalis, and a mercurial diuretic will be more effective than any cough mixture

BRUCELLOSIS

THE exact prevalence of brucellosis (undulant fever) in this country is not known, because it is not a notifiable disease, but Dalrymple Champneys[1] estimates that there are at least 500 cases annually Drinking raw milk is probably the commonest mode of infection, although farm labourers, veterinarians, and laboratory workers exposed to infection may and often do contract the disease The risk of brucellosis must be assumed whenever cow's milk has not been pasteurised or boiled In a series of 1134 cases reported by Dalrymple Champneys, 780 patients were known to have consumed unboiled or unpasteurised milk or cream, even tuberculin-tested milk cannot be assumed to be free from infection

Brucellosis must always be considered in any persistent pyrexia, or obscure febrile illness There is usually a prodromal period in which the patient complains of tiredness, frontal or occipital headache, and sweating, accompanied by a characteristic sour odour, although, on the other hand, the onset of the disease may be extremely sudden Anorexia, muscle pains, particularly in the lumbar region, arthralgia, rigors, an enlarged spleen, and constipation or digestive disturbances are common A lymphocytosis and polymorphonuclear leucopenia are often present The diagnosis is confirmed by the culture of *Brucella abortus* from the blood, or by an agglutination test, using a standard brucella antigen, to a titre of not less than 1 in 100 Cross agglutination may cause confusion in tularæmia and cholera, but this is of no significance in this country, though it is in the East and in America An intradermal test using "brucellin" or "brucellergen" is sometimes used as an aid to diagnosis There are often no clear cut symptoms, and brucellosis is sometimes diagnosed clinically as influenza, typhoid fever, tuberculosis or malaria, and in fact it may be confused with any pyrexial illness with few physical signs, the differentiation between brucellosis and typhoid fever may be particularly difficult Moreover the duration of the illness and the way it ends are variable Even in the absence of specific treatment the disease may last only a few days or weeks, or it may become chronic and last for years

A great many remedies have been tried in brucellosis vaccines, antisera hyperthermia blood from immunised subjects, 'brucellin" (made from the filtrate of a broth culture of brucella) and the sulphonamides have done little good But the newer antibiotics hold much more promise, and their value is now becoming established There seems to be little to choose between aureomycin, chloramphenicol, and terramycin[2–5] Streptomycin in doses likely to be effective is too toxic The relapse rate, using single antibiotics, is, however, high, in a series described by Killough et al[5] it was 69% But a big reduction in the relapse rate can be achieved by using antibiotics in combination Herrell and Barber[6] reported favourably on a combination of aureomycin and dihydrostreptomycin Magill and Killough[7] used a combination of terramycin and streptomycin (or dihydrostreptomycin) for a period of three weeks The initial response was good and the relapse rate was reduced to 14% The well known effects of cortisone on pyrexia and arthralgia suggest that it might usefully be combined with one of the antibiotics in acute brucellosis

There are hopes that contagious abortion in cattle, which is also caused by *Br abortus*, as well as brucellosis in man, may be stamped out by the vaccination of cattle with what is known as strain-19 vaccine This is having a great success in reducing the prevalence of contagious abortion, which is now down from something like 40% in herds in this country to about 15%[8] Eradication of the disease in cattle by slaughter can never be an economic means of control in Britain, where the infection is so common The present legal position is that no one may sell milk from a cow knowing that it is suffering from contagious abortion, but, as the presence of *Br abortus* would need to be demonstrated before the offence could be proved, the enforcement of the law is difficult At the moment there is only one sure method of prophylaxis against brucellosis—to boil or pasteurise all milk before consumption

THE CLIMBING OF EVEREST

THE good news from Colonel Hunt and his expedition on Mount Everest reached London on the eve of Coronation Day and this splendid addition to the excitement of the occasion was all the more stirring because earlier messages had suggested that the mountain's formidable barriers had again beaten back the climbers In the first strike for the summit, on May 25, Bourdillon and Evans used the closed circuit oxygen apparatus We do not know how far the difficulties that deterred them were the result of oxygen lack but certainly the closed circuit has not been so thoroughly tested under these extraordinary circumstances of weather and terrain as the more familiar open circuit apparatus And it was with open circuit apparatus that Hillary and Tensing left camp VIII, on the ridge below the South Summit, to grapple triumphantly with the last 1200 feet on May 29 Judging from the stories that have so far been told,[9] oxygen supply was the greatest worry for those who climbed from camp VII on the South Col, for the weather, so cruel to many of the earlier expeditions, seems to have been comparatively gentle this time The success of Colonel Hunt and his men owes much to the skill of those who planned the oxygen equipment and the other aids to survival and strength at great heights, and to the rugged Sherpas who carried the necessary supplies of oxygen up to the South Col—itself a dreadful mountaineering feat The members of the expedition are now descending the slopes they have conquered Colonel Hunt and Mr Hillary to be knighted by the Queen Sherpa Tensing to receive an honour not yet announced and the whole party to be acclaimed for their courage and endurance

REPLACEMENT OF BOTH URETERS BY AN ILEAL GRAFT

J. Foret
M.D. Liége

C. Heusghem
Ph.D. Liége

From the Department of Urology and the Medical Laboratory of Chemical Research, University of Liége, Belgium

A woman, aged 29, had been treated several times for bilateral stenosis of the ureteral meatuses. This stenosis led to gross enlargement of both ureters and the pelvis of one kidney and consequent progressive destruction of the parenchyma of both kidneys. After the failure of various measures we performed a bilateral nephrostomy on Feb. 9, 1952, followed on Feb. 23 by resection of 50 cm. of ileum near its terminal portion. The remaining portions of the ileum having been anastomosed, the resected portion, with its mesentery, was drawn towards the bladder and arranged in a U-shaped loop. The base of this loop was anastomosed with the bladder, and two lateral limbs were substituted for the pelvic and iliac portions of both ureters. The remaining portions of the ureters were then anastomosed with the free lateral ends of the resected ileum (fig. 1).

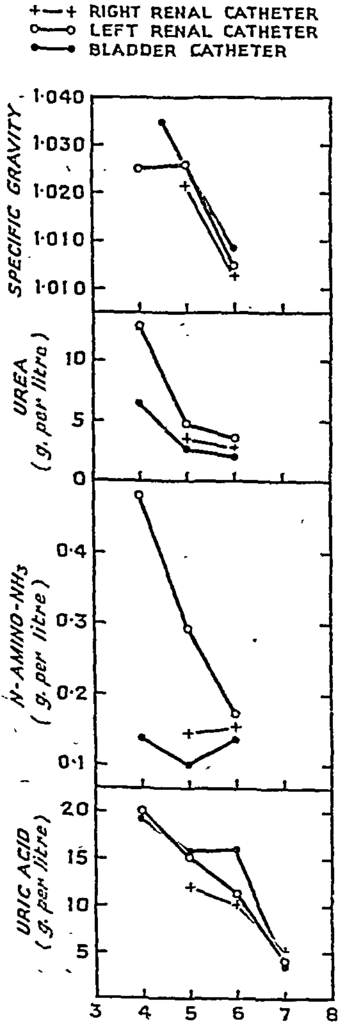

Fig. 2—Analysis of postoperative urine.

In the immediate postoperative period we collected the renal urine through nephrostomy catheters. After the third postoperative day, by temporarily obstructing these catheters we collected the vesical urine which had passed through the ileal loop.

The collected urine was examined for density, total nitrogen, urea, N-amino-NH_3, uric acid, and free and total creatinine. The electrolytes could not be determined daily, because of difficulties of collection. Fig. 2 shows the changes in specific gravity and in amount of urea, N-amino-NH_3, and uric acid. In our opinion this is the most important part of the postoperative problem.

It can be seen that, after the fifth postoperative day, the amounts of the main nitrogenous urinary compounds excreted began to approach stability, which was reached on the seventh or eighth postoperative day. The composition of the bladder urine, although disturbed at first, gradually became similar to that of the urine collected through the renal catheters. This indicates that the grafted section of ileum had become well adapted to its new function, with altered permeability. It became adapted to the flow of urine without producing any troubles except transient ones.

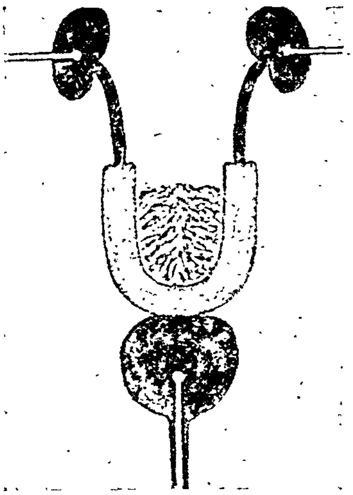

Fig. 1—Scheme of operation, showing ileal loop anastomosed to ureters and bladder.

Twelve months after the operation the patient has recovered normal micturition and a perfect state of health. She presents no biological abnormalities, and the renal function and pyelographic appearances have shown impressive improvement.

The complicated experimental conditions met with in such a case contribute to making the interpretation of our results difficult. Further research should be undertaken on this subject, directed at a more complete and precise study of the postoperative period of adaptation, especially as regards what is added to, and what is absorbed from, the renal urine by the intestinal graft.

HERPES-SIMPLEX HEPATITIS AND ENCEPHALITIS IN NEWBORN TWINS

N. E. France
M.B. Wales
ASSISTANT PATHOLOGIST, QUEEN ELIZABETH HOSPITAL FOR CHILDREN, LONDON

Mary J. Wilmers
M.D. Lond., F.R.C.P.
PHYSICIAN, CHILDREN'S DEPARTMENT, SOUTH LONDON HOSPITAL FOR WOMEN AND CHILDREN

Evidence has been produced confirming that a pathologically distinct form of hepatitis, first described by Hass (1935), is the result of infection by the virus of herpes simplex (Quilligan and Wilson 1951, Zuelzer and Stulberg 1952).

Although virological studies were not made in the present cases, they correspond pathologically to those previously reported and are of interest in that they suggest the possibility of transplacental infection. We have been unable to find reports of any similar cases in the British literature.

CASE-RECORDS

A woman, aged 28, gave birth a month prematurely to binovular twin boys at the South London Hospital for Women and Children on Nov. 3, 1946. She had had a pregnancy, four years before, terminating spontaneously at six months with the delivery of stillborn twins, one of which was macerated. Her present pregnancy was complicated by hypertension (160/95–100 mm. Hg) during the last month;

JUNIOR HOSPITAL STAFFING

A MEDICAL VIEWPOINT

R M. Forrester
M A M B Camb, M R C P

When the National Health Service was established in 1948 it was clear that there would be many aspects needing review and revision It can hardly have been foreseen, however that after less than five years some sections of the hospital services would be within sight of breakdown because of shortage of junior medical staff This is nevertheless the problem which is troubling regional boards The first public indication was given in the House of Commons in 1951 [1] and the continued anxiety is reflected in letters reaching the medical press

An indication of the size of the problem came from the Manchester region in November 1951, when out of 570 posts (intermediate registrar senior house officer, and house officer) only 417 were filled—a deficiency of 27% [2] Of intermediate registrar posts 19 5% were unfilled, despite the fact that the regional board was trying to fill an establishment some 8% less than the minimum they had declared necessary a few months earlier There has since been very little change in the state of affairs

Regional boards find that the problem is worst in small peripheral hospitals but even in teaching centres some specialist hospitals are in difficulty In 1952 the Royal Manchester Eye Hospital had a quarter of its resident posts unfilled, and today there is only one resident out of the normal complement of five

It seems strange that this shortage should be present at a time when the medical schools of the United Kingdom are steadily increasing their output of doctors and when the total number of registered practitioners is rising rapidly (1932, 56,007, 1942, 69 428, 1947, 77,929, 1952, 83,914)

THE PAST

To understand the present position it is necessary to review certain aspects of the history of the hospital services since 1948

At the outset it was accepted that every general practitioner needed at his elbow a comprehensive specialist service to take the place of the uneven and inadequate service that had hitherto been provided in the lesser centres of population Much of the peripheral specialist work had been done by general practitioners themselves and many of the general-practitioner specialists were of the highest standing Rightly or wrongly, however, it was decided that the over-all quality of the service left much to be desired, and vast expansion of the specialist service was proposed Thus the divorce between hospital and general-practitioner services was arranged, and the great post-war hospital boom began There was talk of a "three-tier system" by which every hospital bed was to be watched over by consultant, registrar, and houseman The urge to increase medical staff in established units was stimulated It became a matter of competition between established consultants to build up the numbers in their teams

The flood of ex-Service doctors made it easy to find the man-power, and so the inflation of the service continued almost unchecked until the Ministry of Health published their memorandum on the registrar grades in November, 1950 This pointed out that there were at that time over 1400 doctors in each of the senior and intermediate registrar grades, and it was clear to everyone that the numbers bore no real relation to the eventual prospects of specialist posts The drastic Ministry proposals for reducing the numbers were acceptable neither to the profession [3] nor to Parliament [4], but it was clear that some attempt had to be made to achieve a balanced establishment It was agreed after discussion between the profession and the Ministry that for England and Wales the establishment of senior registrars should not exceed 960

This figure was based on a normal tenure of four years, and was reckoned to allow 75% of senior registrars the prospect of a specialist post Intermediate registrar establishments were left to the discretion of the employing authorities, whose ideas may be exemplified by those of the Manchester Regional Hospital Board In February, 1951, this board, which had on their staff 122 intermediate registrars, suggested that in fact 150–200 were needed in the non-teaching hospitals of the region to provide a moderately satisfactory service [5]

Here, then, in early 1951 was a hospital service gradually expanding with new specialist appointments still overloaded with registrars (there were three grades at that time) and moderately well staffed farther down the scale by hopeful house-officers who thought they might be on the road to a specialist career It must have been shortly after this that it began to occur to newly qualified and newly demobilised doctors that hospital work held a future for only a very limited number As early as July 1951 the first real signs of staff shortage were apparent, and *Lancet* editorials [6] drew attention to the serious lack of applicants for junior hospital posts Now in 1953 a steadily deteriorating position is said to be occupying the attention of the Minister of Health [7]

THE PRESENT

It seems quite clear that the flood of recruits to the hospital service in the post-war years is unlikely to be repeated They were swept in on a tide of optimism and expansion, and postgraduate deans were advised by the Ministry of Health to encourage large numbers of doctors to take higher degrees The success of this campaign may be judged from the figures of the Royal College of Physicians Over the period 1932–35 an average of 67 new members were admitted each year in 1948–51 the average was 269 per year

The new generation of doctors study the past and the future more carefully and this is the picture that they see Before the start of the health service the routine work of many hospitals was supervised by the senior resident, who had the title of resident medical (or surgical) officer Many such residents gained great experience and some of them higher degrees, but few had any illusions about their prospects of eventual specialist status They were, however anxious to have this experience because they knew that with such a background it would not be difficult to find a general practice—often in the vicinity of the hospital—where they would be welcomed Commonly too, they had a chance of returning to their own or another hospital as part-time specialists The numbers of men involved were small, the opportunities adequate, and a steady supply of labour was available to satisfy the modest demands of the hospital service of the time With the National Health Service there have been great changes Gone is the incentive to acquire experience and higher degrees before entering general practice No longer can the young man with his F R C S settle in practice and do some surgery The hospital beds now belong to the new consultant, and in many areas the general practitioner is prevented from having even the but albuminuria was noted for the first time only after labour had begun. The Wassermann reaction was negative and her blood-group was Rh-negative, but no antibodies were found in her serum.

Three days before delivery she developed severe generalised urticaria, with intense pruritus, which was considered to be a toxic rash. Labour started 2 days later and lasted for twenty-eight hours, the first infant being delivered by the vertex and the second by the breech. Twelve hours after delivery the urticaria was still severe and she developed pyrexia (103°F) accompanied by a rigor and delirium. Her temperature returned to normal within twenty-four hours, her skin improved, and she made a good recovery.

TWIN 1

Twin 1, a boy weighing 5 lb. 1 oz., was slightly cyanosed at birth, but rapidly improved and remained well until the 4th day of life, when mild jaundice appeared and he had two attacks of vomiting, followed by cyanosis, rolling of the eyes, and twitching of the face. His temperature rose to 100·4°F, this being the only occasion throughout his illness on which it was raised. The following day he had a further cyanotic attack and four attacks of twitching in spite of chloral-hydrate therapy. On the 7th day he no longer took his feeds and had four severe convulsions each lasting two or three minutes. He finally became deeply cyanosed and died at the age of 7 days.

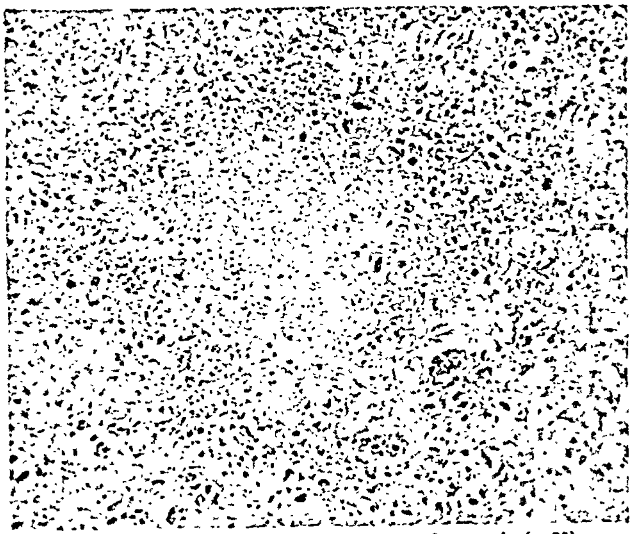

Fig. 1—Liver of twin 1, showing a focus of necrosis (×90).

Necropsy Findings

The *liver* was very firm and of about normal size. Numerous round white nodules were scattered evenly beneath the capsule but did not project above the surface, which remained smooth and glistening. Similar areas were present on the cut surface, varying in size from 0·5 to 2·0 mm. in diameter, most of them being about 1 mm. in diameter. They were diffusely distributed and bore no obvious relation to any particular region of the lobule. The *gall-bladder* contained normal green bile and the extrahepatic bile-ducts were patent. The *spleen* was slightly enlarged, but showed no abnormality. The *brain* was too diffluent to allow of detailed examination.

Microscopy

The *liver* showed extensive areas of necrosis of irregular size and shape (fig. 1). Although most of the lobules showed central necrosis only, in others the necrosis extended to the portal tracts or even involved several adjacent lobules. The necroses were all recent, judged by the persistence of the necrotic cells in situ and the absence of any great reaction to their presence. Bordering on the necrotic patches were occasional degenerate hepatic cells intermingled with viable cells. The degenerate cells were often irregular in outline and had more eosinophilic cytoplasm than normal. There was often a round, oval, or irregular and eosinophilic or faintly basophilic homogeneous structure almost completely filling the nucleus. Occasional cells showed condensations of chromatin on the nuclear membrane separated from a rather irregular eosinophilic inclusion body by a clear halo (fig. 2). All the other organs were normal.

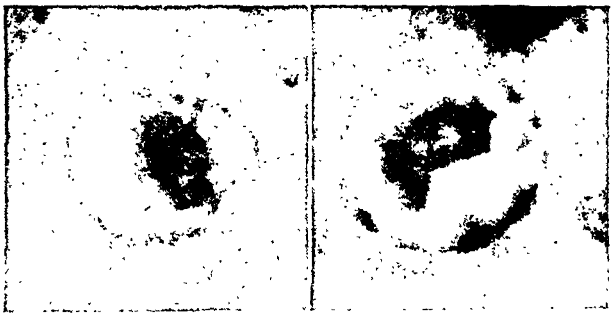

Fig. 2—Liver cells showing classical shrunken eosinophilic inclusions (×2100).

TWIN 2

Twin 2, also a boy, weighed 5 lb. 3 oz. and was well until the age of 10 days, when he was found to have lost 3 oz. during the previous twenty-four hours, his weight having fallen to 4 lb. 10 oz. No abnormalities were detected clinically, and there was no jaundice. Next day he became lethargic and reluctant to feed. He gained weight slowly until the 16th day of life, when he passed two motions containing a streak of bright blood. His colour became poor, and twelve hours later he had a convulsion accompanied by the passage of bright blood per rectum, and died at the age of 16 days.

Necropsy Findings

The *liver* was like that of twin 1. The *brain* was externally normal, but on section numerous white nodules, similar to those in the liver, were seen scattered throughout both cerebral hemispheres. They were present in both grey and white matter and involved the basal ganglia. Owing to their firmness they could be easily distinguished by touch from the surrounding brain tissue. There was no evidence of hydrocephalus or of meningitis. All the other organs appeared normal.

Microscopy

The *brain* showed areas of gliosis of different sizes. Such areas were widespread and lay in both grey and white matter, bearing no relation to the vessels. Many were tiny foci of small cells with deeply staining round nuclei almost completely filling the cells; others were more extensive and composed of numerous glial cells, resembling astroglia, together with smaller cells, some of which appeared to represent degenerate astrocytes (fig. 3). Gliosis was prominent beneath the ependyma of the lateral ventricles, and in some places the proliferated neuroglia had extended through the ependyma to produce small nodules on the lining of the ventricles. Less common were small patches of softening in

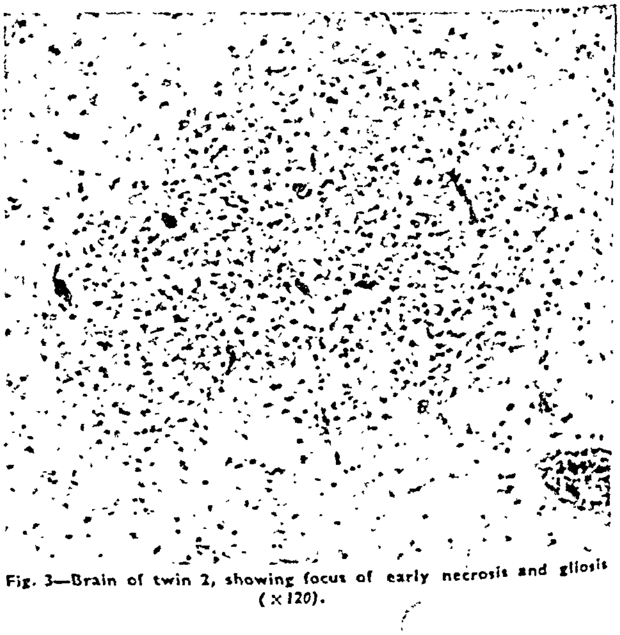

Fig. 3—Brain of twin 2, showing focus of early necrosis and gliosis (×120).

simplest investigation made on his patients Instead, for even a blood-count his patient must go through the formalities of an appointment with a consultant and so do his bit towards the overcrowding of an outpatient department already working below establishment for lack of a registrar This is a situation which Alice would have taken in her stride, but in the daylight outside the rabbit hole it is plainly ridiculous It certainly does not provide inducement to the young doctor to gain experience To this must be added the belief among registrars that to general practitioners the ex-registrar is necessarily a "failed specialist" who proposes to take to general practice as a poor second choice This is a regrettable attitude, but who can blame a principal if, under the present circumstances of general practice and its divorce from hospital work, he selects a man of 28 with a diploma in preference to a man of 38 with "F R C S—10 years' hospital experience"? So much, then, for the prospects in general practice

What about the future for the one in every four of intermediate registrars who may hope to become a senior registrar? His chance of becoming a specialist in some grade is now increased to 75%—but every step in this direction takes him farther away from the possibility of general practice as a reasonable alternative And what for the lucky few who do eventually reach specialist posts? At the end of 1951 there were 2445 whole time specialist medical and dental officers (including senior hospital medical officers and senior hospital dental officers)[7] A study of *The Lancet* for 1952 reveals that of the 887 specialist posts advertised that year 655 were full time It is idle to suppose that more than a small fraction of the doctors now in these posts will ever move on to maximum part-time posts The S H M O s among them are limited to the salary scale £1300–1750, and the full time specialists to £1700–2750 —without private practice, domiciliary visits, or reasonable income-tax allowances Fair salaries these may be for the work involved, but they are not the glittering prizes which induce a young man to commit himself to a specialist training—especially when compared with the money he is encouraged to earn as a partner in general practice According to *The Lancet* he can hope to achieve such partnership by the age of 36,[8] and with 2000 patients on his list his income from this source alone would be £2200[9] A man with a family may wisely decide that the D OBST and an ultimate £3000 offers better professional satisfaction than the M D, M R C P, and £1750 The general practitioners have arranged their affairs well and no one will begrudge them their award, but they have seriously undermined the hospital services

In addition to their financial handicaps specialists at peripheral hospitals are in an exceedingly difficult position because of the shortage of resident staff Were it not for the present unhappy situation of many senior registrars there might be considerable difficulty in filling some of the single-handed specialist posts

Never was there a bleaker prospect for the young man starting a hospital career Here lies the root of the hospital staffing problem

THE FUTURE

What are the possible remedies for this state of affairs? It is necessary to explode at once the myth that the year of compulsory preregistration residence will be of any real help in staffing hospitals A recent survey (July 1, 1951, to June 30, 1952) showed that 76 5% of all doctors entering the Armed Forces during that period had done at least a year in hospital posts and at least 27% had done considerably more than this

The Medical Act, 1950, will ensure that all doctors do a full year in hospital, but at the end of his year each liable individual will be called up unless there is some very special reason for his further deferment At the moment the need of a hospital for his services is not regarded as a valid reason In addition it must be recalled that preregistration appointments are in approved posts in the major specialties (medicine, surgery, obstetrics) It is difficult to see how the Medical Act makes any real contribution to the staffing of peripheral hospitals, and it will certainly not improve the figures for S H O s and registrars

The main solution must come from recognition that for the doctor a junior hospital post is a temporary affair For the hospital "the house surgeon" is a permanent need, but for the doctor the post is a stepping stone It must be made an effective step either to a career as a specialist or a career as a general practitioner

As far as specialisation is concerned, I have already pointed out that the balance of financial reward in general practice and specialist medicine needs redress Attention must be paid to the particular handicaps imposed on the full-time salaried specialist—whether of consultant or S H M O status—and the trend towards increasing the number of whole time appointments must be reconsidered Any attempt to introduce a new grade of specialist paid at a lower rate would certainly aggravate the position, for, although some posts might be filled now by ex senior-registrars, their existence would provide no incentive in the future

Apart from the eventual financial reward every effort must be made to ensure that the scales of promotion are not too heavily weighted against the man whose registrar experience has been gained at non teaching hospitals This problem will be solved, as far as senior registrars are concerned when the majority of senior registrar posts are held on a basis of rotation between teaching centre and periphery Such rotation hardly seems practicable for intermediate registrars who work on a 2 year tenure, and it must be acknowledged that the registrar from a teaching hospital will always be a strong candidate for a senior registrar post Here the interests of the registrars themselves as well as those of the peripheral hospitals might be best served if the teaching hospitals insisted that experience *as a registrar* in a non teaching hospital was a necessary qualification for appointment to a similar grade at the teaching centre There may well be other ways of tackling this side of the problem

As far as general practice is concerned, we are up against a much more formidable problem The opening of diagnostic facilities to general practitioners would be a first step which would make the background of hospital training a clear asset in practice Much more fundamental however, is the reintegration of the specialist and general practitioner services By this is not implied that regular contact between the G P and the specialist which is so hopefully discussed and so seldom achieved, but rather the replanning of the whole structure of hospital staffing at all levels to allow the general practitioner specialist to return to the scene Only by holding out the very real prospects of such posts will it be possible to fill those 75% of intermediate registrar posts which must in future be held by potential general practitioners

The British Medical Association are committed to this policy,[10] but improvement will not be brought about by grafting clinical assistants and part time G P consultants on to the present establishments There must be a complete reconsideration of the method of staffing at all levels The medical and political advice upon which the hospital service was initiated must now be reviewed, the lessons of the last five years learned, and the harsh facts faced for the first time since its inception which a few compound granular corpuscles were present, together with evidence of mild neuroglial proliferation at the periphery of the lesions. In neither the areas of gliosis nor in those of softening were any intranuclear inclusion bodies seen.

---

[8] *Ibid* April 18 p 779

[9] *Brit med J* suppl 1952 i 28

[10] *Ibid*, p [illegible]

The *liver* and all the other organs showed histological features similar to those of twin 1.

DISCUSSION

Cowdry (1934) called certain intranuclear inclusion bodies "type-A inclusions" and thought them characteristic of infection by a virus. Cells containing such inclusions show accumulation of chromatin on the nuclear membrane, which is separated from a central intranuclear eosinophilic body by a clear zone. The cell ultimately disintegrates completely, and such cells are accompanied by a noticeable reaction in the surrounding tissues. Those associated with herpes simplex have been described by Scott et al. (1950), who state that when the inclusions first appear they are faintly basophilic and fill the entire nucleus; later, shrinkage takes place, and an eosinophilic body is produced, separated from the nuclear membrane by a clear halo.

Primary infection by the herpes-simplex virus commonly produces gingivo-stomatitis in children (Scott 1944), usually resolving after 1 to 2 weeks. Although rare in the neonatal period, primary infection is important in that it may produce lesions in organs other than the skin, and may cause death (*Lancet* 1952).

Although herpes simplex had for some years been suspected on morphological grounds as a cause of encephalitis, it was not until 1941 that Smith et al. (1941) isolated the virus from a child dying at the age of 5 weeks with extensive meningo-encephalitis in whose brain typical inclusion bodies were found in the nerve-cells. Since then the virus has been recovered from the cerebral lesions of two adults (Zarafonetis et al. 1944, Whitman et al. 1946) and from an infant aged 13 days born at full term of a woman who had genital herpes in the fifth month of pregnancy (Wildi 1951).

Wildi's case showed cerebral lesions of two types: in one there was non-specific inflammation and no inclusion bodies; and in the second type inclusion bodies were very numerous, especially in nerve-cells, and associated with much inflammation and necrosis. The specific ætiology of the lesions found in twin 2 is suggested by the associated presence of typical herpes hepatitis, although no inclusion bodies were found in the brain. Haymaker (1950) states that softening of the brain may be so severe that the pathologist omits histological examination; the possibility remains that encephalitis caused the diffluence of the brain of twin 1.

That herpes-simplex virus can produce lesions in organs other than the brain was first suggested by a case reported by Hass (1935). This was in a girl aged 14 days who had been born prematurely, and numerous necrotic areas were found throughout the liver, which on microscopy revealed many cells containing intranuclear inclusions resembling those found in herpes simplex. Similar microscopic foci of necrosis were also present in the adrenal glands.

Quilligan and Wilson (1951) described a similar case in a child aged 12 days, whose mother had herpes labialis 9 days before delivery. The baby showed herpetic lesions of the skin and, at necropsy, severe hepatitis with inclusions in the liver cells. The virus was isolated from the skin on the 2nd day of illness, and from the skin and liver at necropsy.

Zuelzer and Stulberg (1952) reported eight cases of generalised visceral lesions which were due to the herpes-simplex virus and in which hepatitis was a prominent feature. Their material was divided into two groups:

(1) Five babies who died 5 to 13 days after birth. Three of them were thought to have been infected during passage through the birth canal, thus acquiring herpetic conjunctivitis; in one case transplacental infection was suggested. The mother had clinical genital herpes simplex in one case, and the virus was isolated from her infant.

(2) Three older children in whom generalised spread followed herpetic gingivo-stomatitis.

As neither of the present cases showed any obvious portal of entry we believe that the infection was transplacental.

SUMMARY

Twin boys dying at 7 and 16 days showed the pathological features of herpetic hepatitis, associated in one case with encephalitis.

The ætiology of this condition is discussed.

We wish to thank Miss F. M. Humphries for technical assistance.

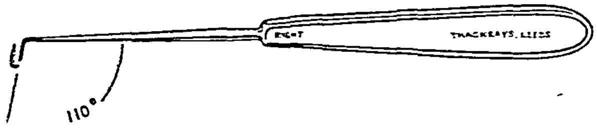
New Inventions

FEMORAL-HERNIA NEEDLE

THE common approaches for repairing femoral herniæ are the inguinal approach of Lotheissen and the older route below the inguinal ligament. After the hernial sac has been excised, an essential step in both methods is to pass two or three stitches through Astley Cooper's ligament. This is often done with a small-sized Symonds or J-shaped needle held at an angle of about 110° in a needle-holder. As such a needle is difficult to hold and to control, I use the needle shown in the illustration and find it simplifies the operation.



My own practice is to repair the non-strangulated femoral hernia by the lower route. It is a quick easy operation which does not weaken the inguinal canal by dividing the transversalis fascia. For strangulated hernia the inguinal route is preferred because it enables the strangulated bowel to be inspected and, if necessary, resected. In both operations two or three no. 35 unbleached linen-thread sutures are passed through Astley Cooper's ligament. Linen is chosen because it is strong, knots well, and being of vegetable origin is absorbable. In other parts of the body, where I have had opportunities of reopening the incision, thread takes about eighteen months to be absorbed. In contrast to 'Nylon' it encourages fibrosis. If sepsis is feared in a strangulated hernia, antibiotics, catgut, or nylon can be used, because infected thread is not absorbed and may cause a sinus to be formed.

In the lower operation Cooper's ligament is brought into view by retracting the inguinal ligament by passing a Kocher's blunt dissector or a narrow copper spatula through the femoral canal so that its end bears on the posterior surface of the pubic bone. If the lower half-inch of the copper spatula is bent to 60°, a better exposure is obtained. The femoral vein is protected with a Lane's retractor or with a finger. Since the sutures are inserted with the handle of the needle placed medially across the midline of the body, a separate needle is required for

Now at last there must be in this staff shortage, common ground between politician, bureaucrat, and doctor The time is surely ripe for realistic discussion and action

I am grateful to Dr John Walton, Dr E Grey Turner, Dr F J Harvey, and the registrar of the General Medical Council for various items of fact included in this article

SALARIES OF ASSISTANT MEDICAL OFFICERS

UNDER an Industrial Court award which operates as from June 1, the salary-scale of assistant medical officers or medical officers in departments is to be £950, rising by annual increments of £50 to £1300 This award supplants a 1950 award[1] by which the scale was £850 rising by annual increments of £50 to £1150 In seeking revision of the 1950 award the staff side of Whitley Council Medical Committee "C" claimed a scale of £1000 rising by annual increments of £50 to a maximum of £1400

The new scale is to be applied to the present holders of appointments Assimilation on the new scale will correspond with the medical officer's position on the old scale, but a medical officer now at the maximum (£1150) of the old scale is to be placed at the sixth point (£1250) of the new scale and thereafter will proceed to the new maximum

The salaries of other medical workers in the public-health service are governed by earlier decisions of the Industrial Court[1 2]

THE HEALTH OF A TROPICAL PEOPLE

A Survey in Ceylon

H. CULLUMBINE
M.D M.Sc Sheff
LATE PROFESSOR OF PHYSIOLOGY AND PHARMACOLOGY,
UNIVERSITY OF CEYLON, COLOMBO

III INCOME AND HEALTH

THE income of the individual or of the family is often used as an index of social environment It is an index which can be given a quantitative rating which is easily checked, and which is readily understood by all.

The income includes not only wages earned but also food and goods produced for family use, profits from investments, and an allowance for rent if the house is self-owned. When estimating the income all these sources should be checked and then counter-checked by reference to the employer and other interested parties For the household the total income may be reduced to so much a head, or it may be related to the number of food-consumption units in the household In Ceylon we have used the latter method because it enabled us to link the income classification with the dietary studies

An Inquiry Based on Income

In Ceylon, we usually divided our samples into three income groups:

(1) *Low income group* in which the families have an income of less than 20 rupees per adult food-consumption unit per month

(2) *Intermediate income group* in which the families have an income of between 20 and 50 rupees per adult food-consumption unit per month

(3) *Higher income group* in which the families have an income of more than 50 rupees per adult food-consumption unit per month.

TABLE I—AVERAGE INTAKE PER CONSUMPTION UNIT (INTERNATIONAL VALUES) PER DAY

—	Low incomes (441 families)		Intermediate incomes (681 families)		Higher incomes (185 families)	
	Mean consumption	S.E. of mean	Mean consumption	S.E. of mean	Mean consumption	S.E. of mean
Calories	2067	49·5	2593	48·5	3055	93·1
Protein (g.)	57·8	1·34	75·2	1·63	87·8	2·85
Fat (g.)	31·8	1·72	52·7	1·68	91·0	4·55
Carbohydrate (g.)	396	7·1	476	9·7	493	12·0
Calcium (mg.)	396	14·7	579	13·6	756	24·0
Phosphorus (mg.)	1475	51·4	1730	51·0	2080	51·7
Iron (mg.)	12·9	0·39	16·8	0·38	18·1	0·62
Preformed vitamin A (I.U.)	3180	103·2	4670	120·2	5700	331·0
Thiamine (mg.)	0·919	0·027	1·352	0·079	1·365	0·049
Riboflavine (mg.)	1·433	0·058	2·052	0·044	2·321	0·038
Nicotinic acid (mg.)	11·02	0·587	13·0	0·288	13·62	0·464
Ascorbic acid (mg.)	48·1	2·99	51·0	1·67	90·5	4·42

S.E. = standard error I.U. = international unit.

The low income group, which is the largest, contains mainly agricultural workers and the village peasant cultivators The intermediate-income group is predominant in the urban areas and on the estates and includes most of the estate labourers and clerical workers The higher-income group is found chiefly in the urban community, and includes the professional classes, the civil servants business men, and people from the supervisory grades of labour

CONSUMPTION OF FOOD

A sample survey of the whole island showed that the quantity and quality of the food eaten was largely determined by the economic status of the family (tables I and II) (Cullumbine 1951)

The calorific value of the total foodstuffs consumed, and the total amounts of the individual chemical constituents consumed, rose with the economic status of the consumers The variation in the consumption of individual foodstuffs with economic level is not so con-

TABLE II—AVERAGE DAILY INTAKES (OZ.) PER CONSUMPTION UNIT (INTERNATIONAL VALUE)

—	Foodstuffs	Low incomes (441 families)		Intermediate incomes (681 families)		Higher incomes (185 families)

each side: these needles are marked "right" and "left."

I normally pass three sutures through Cooper's ligament and next rethread the needle to the upper end of each thread. A finger can often be passed through the femoral canal which has been stretched by the hernia and the half-inch length of the anterior wall of the femoral canal appreciated. The lowest limit of the anterior wall of the femoral canal is in any case indicated anteriorly by the upper cornu of the falciform edge (Hey's ligament). The three sutures are passed in turn, from within the femoral canal, through the lowest part of the anterior wall of the canal. The sutures are then tied, fixing the anterior wall of the femoral canal to Cooper's ligament. This makes a good solid repair and does not distort the line of the inguinal ligament.

I wish to thank Miss Margaret C. McLarty for the clear illustration. The needles were made by Charles F. Thackray, of Leeds.

Reviews of Books

Medical History of the Second World War

The Army Medical Services: Administration. Vol. I. F. A. E. CREW, M.D., F.R.S., professor of public health, University of Edinburgh. London: H.M. Stationery Office. Pp. 530. 50*s*.

THIS is a difficult book to review. The title is forbidding and the letterpress relieved only by a few pages of photographs of recruits in training. The subject is one which is unlikely to raise the pulse-rate of many of those who, willingly or otherwise, spent the war years under the motto *Per arduis fidelis.* It was so easy in our troubles to blame "them"—the gilded ones who came and left in large cars, who sent us hither and thither "forthwith," who settled our hash for good or ill. Twelve years or so later we can judge them with charity and, if we read this book carefully, with sympathy. It is not easy to manage a hospital: how much more difficult to manage a hundred hospitals, a hundred field ambulances, and a huge variety of other units, not in one country but scattered from the Falkland Islands to Manipur Road, and often in transit. These had to be staffed and administered by doctors from every walk of the profession, most of whom had been their own masters for years and were proud of it. The regular soldier upon whom fell the brunt of administration in the early days knew little more of the problems of war than the ex-civilian. The R.A.M.C. in peace was a hospital service; stretcher drill was an elegant manœuvre and the recruit knew the First Field Dressing only as a picture on the blackboard. Most of us who laughed or cursed in the autumn of 1939 had reason to be grateful to the regular soldiers who saved us from the major errors of procedure and behaviour. What we did not know then we can learn from this book.

The uncertainty in planning the medical services of the nation for war makes a sorry story. The pull-devil-pull-baker between the Armed Forces and the Ministry of Health took place across the Cabinet table. The first knew the number of doctors needed for the fighting Forces in being and projected, and perhaps they over-estimated their needs. The second had been warned of astronomical casualties from aerial attack at home and believed that they could not spare a man. Perhaps not so much harm would have been done if the fight had been settled twelve months earlier, irrespective of the issue. The finest testimony to the Army Medical Department is that, by the end of 1939, 61 fully equipped medical units had reached France while the health of the Army at home, left in the hands of the ill-trained and uninstructed, gave no reason for anxiety. All this is described critically and without acrimony, but it is past history. Yet there is much in this book which may be read with profit today. Our present problems are not identical but they are not so dissimilar that we cannot draw a parallel: too much to do, too many conflicting claims, not enough willing hands, and, above all, not nearly enough earnest minds willing to give and take responsibility. On a more technical level, the statistical appraisal of medical man-power might be applied to some staffing problems today, and some appreciation of the theory behind the military attempts at rehabilitation might lead to a more objective and less chancy approach to the problem than seems usual.

There is much more in this book which deserves attention. Is there any other country which would entrust an official military history to a distinguished geneticist who now holds a chair of public health? To quote the preface "the author alone is responsible for . . . the opinions expressed." They are shrewd and they aim straight, but they are fair and, as far as we may judge, they will be generally accepted. As an enlightened presentation of fact the book is a masterpiece.

Cardiography in General Practice

ABRAHAM I. SCHAFFER, M.D., assistant visiting physician, Metropolitan City Hospital, New York. Baltimore: Williams & Wilkins. London: Baillière, Tindall, & Cox. 1952. Pp. 135. 24*s*.

THE term "general practice" may not have the same connotation in the U.S.A. as it has here, but in this country the title of this small book must be called misleading. It is a technical account of cardiography, including electro-, vector-, and ballisto-cardiography, illustrated by diagrams to show the electrical changes, normal and abnormal, in the heart and their cardiographic representation, the appropriate placing of leads, and so forth. It is presumably intended for the student aspirant to whole-time cardiology; and even for him it is of academic rather than clinical value, though the cardiographic pictures of the various lesions and disorders of the heart are duly shown. The book shows clearly enough in how many conditions a cardiogram, expertly interpreted, can assist diagnosis; but most practitioners are probably ready to take this on trust, and only those among them determined to understand for themselves the mysteries of cardiographic script will be recompensed for the considerable intellectual effort of reading these pages.

Primary Love and Psycho-analytic Technique

MICHAEL BALINT, M.D., M.SC. London: Hogarth Press and the Institute of Psycho-Analysis. 1952. Pp. 288. 30*s*.

Dr. Balint is chiefly interested in the manifestations of human sexuality, especially as derived from the infant's early relationship with its mother, which he calls "primary love," and with the far-reaching effects which this experience has on the formation of object-relations, and, for the patient in psycho-analysis, on the course of the transference, especially in the closing stages. The papers start with one written in 1930, on psychosexual parallels to the fundamental law of biogenetics, in which the evolution of human sexuality and love is considered in relation to a phylogenetic background based on a wide knowledge of biology. The last paper appeared in 1952, and examines sympathetically some of the more recent findings of Mrs. Klein; so it may be said that the book gives a useful and valid conspectus of the developing viewpoints of psycho-analytic theory on its subject matter. It is simply and clearly written.

Office Management of Ocular Diseases

WILLIAM F. HUGHES, JUN., M.D., professor and head, department of ophthalmology, University of Illinois College of Medicine. Chicago: Year Book Publishers. London: Interscience Publishers. 1953. Pp. 452. 70*s*.

Professor Hughes has condensed current teaching on ophthalmic disease into a small and readable volume, though he does not always abide by the implications of his title, wandering off at times into the hospital treatment of glioma retinæ and retinal detachment. Some of the lid operations are also more than most of us would attempt in the surgery. Illustrations are, on the whole, good, but some photographs, such as fig. 89, are not sufficiently clear to demonstrate anything. Certain treatments, such as that of glioma retinæ, are not quite up to date, but, on the whole, the author has achieved what he set out to do: this is a concise and useful volume.

sistent In general, the intermediate-income families eat more cereals, green vegetables, and pulses, while the higher income families eat more root vegetables, fresh fruit, dairy products, meat, and fish

The proportion of the average total calories derived from protein, from carbohydrate, and from rice decreases while the proportion contributed by fat increases with rising economic status (table III)

The high contribution made by carbohydrates, and by rice in particular, shows the lack of variety in the diet of the average Ceylonese This is further emphasised by the meagre quantities of milk, butter, and other dairy products eaten by people at all economic levels

TABLE III—PERCENTAGE OF TOTAL CALORIES DERIVED FROM VARIOUS SOURCES

Income group	Protein	Fat	Carbo hydrate	Rice
Low	14 1	14 3	71 6	48 1
Intermediate	12 2	18 9	68 9	43 3
Higher	11 7	27 7	60 6	36 3

Only a few families were found to eat these foodstuffs (table IV)

The consumption of meat is also small, but fish is a common article of diet Most of the protein of the diet was of vegetable origin (table V) The percentage contribution to the total protein intake made by meat increases with rising income, but the average contribution to the total intake made by fish is more or less the same in all income groups

DEFICIENCIES AND PHYSIQUE

Many members of the families surveyed were examined for signs of deficient nutrition (table VI) Xerosis, ariboflavinosis, and anæmia are to be found more often among the low-income group Dental caries was found in all income groups, phrynoderma (follicular hyperkeratosis) is commoner in the intermediate income group

TABLE IV—PROPORTION OF FAMILIES CONSUMING VARIOUS FOODSTUFFS

Income group	Butter	Milk	Milk powder	Ghee	Eggs
Low	7/441	83/441	17/141	3/141	27/441
Intermediate	24/681	288/681	103/681	28/681	154/681
Higher	51/185	161/185	52/185	31/185	93/185

Physiques and body measurements differed widely in the three income-groups (table VII) Exercise performance ability is correlated with certain anthropometric characters (Cullumbine 1949), and table VIII correlates variations in strength, exhaustion, and speed with anthropometric characters

The differences in body configuration offer a reasonable explanation of the differences in dynamic fitness of the people at each economic level We find indeed the vicious circle—low income, poor nutrition, poor physique, poor functional or working capacity poor production, therefore low income

BIRTH WEIGHT

The low income/poor nutrition/poor physique correlation has other implications An analysis of 1311 consecutive full-term births in one ward of the De Zoysa Maternity Hospital, Colombo, suggested that the main factors influencing birth weight were the mother's weight, the number of gestations and whether the birth is a single or a multiple one (Cullumbine 1950) The heavier the mother the greater was the infant's birth weight, except that when the mothers weighed over 120 lb there was no further increase in the baby's weight with increasing maternal weight This relationship has been generally recognised by obstetricians, and it has also been found to be true in stock breeding (Walton and Hammond 1938) It is usually attributed to hereditary

TABLE V—PERCENTAGE OF TOTAL PROTEINS CONTRIBUTED BY VARIOUS FOODSTUFFS

Income group	Meat	Fish	Vegetables
Low	2 8	24 4	72 8
Intermediate	4 1	21 9	74 0
Higher	11 2	25 1	63 7

TABLE VI—SIGNS OF MALNUTRITION OBSERVED IN THE THREE INCOME GROUPS

Income group	Number of subjects examined	Number of subjects with signs of—					
		Under-nourishment	Xerosis	Phrynoderma	Riboflavine deficiency	Anæmia	Dental caries
Low	1936	575	1119	629	107	1141	697
Intermediate	2876	367	1099	1252	108	1066	908
Higher	583	79	243	173	3	102	182

P = Probability

ychological and prophylactic effect" of inducing dical experts on both sides to be careful in their sertions and claims, because these might always be viewed by an outstanding authority in their own ld.

For some years the State of Massachusetts has provided, civil proceedings, pre-trial examination of psychiatric ses by impartial medical specialists, and this arrangeent is said to be working well. The result of the ew and far wider experiment in New York may well fluence the development of practice in this country. ndeed, no legislative innovation would be required to troduce a parallel working system here, for under the ules of the Supreme Court (R.S.C. 0·37A, r.1) the court r a judge may already "in his discretion at any time n the application of any party appoint an independent xpert (to be called "the court expert") to enquire and eport upon any question of fact or of opinion not nvolving questions of law or construction." Unfortunately, applications under this rule have been but few nd far between, and it would perhaps be well if judges were given power to call in court experts from an ppropriately prepared list even where no such express equest is forthcoming from the parties.

TREATMENT OF BARBITURATE POISONING

SUICIDAL poisoning with barbiturate drugs is becoming increasingly common,[1] and the mortality may be high even in those who come under medical care. Nilsson in Sweden has shown the value of good medical treatment without convulsant drugs,[2] and Locket and Angus in this country have had similar results.[3] In their series of 84 patients who were not given convulsant drugs there were only 2 deaths. Analeptics are not a treatment for anoxia or asphyxia, and their value is obviously difficult to assess when survival may depend on the skill of the nurse and the doctor in managing an unconscious patient. Nevertheless it has become the practice to give analeptics for barbiturate poisoning because they reduce the mortality in poisoned animals; but then experimental animals do not enjoy the nursing attention that is the patient's right.

In comparing different analeptics the effect of chance on mortality-rates cannot be gauged when deaths are numbered in single figures. Mortality-rates depend on age, individual idiosyncrasy, and the condition of the liver and kidneys, as well as on more obvious factors such as the dose and type of the drug and the amount vomited. Hence little is to be gained from comparing the results of different workers, as Koppanyi and Fazekas [4] have done. They conclude in the end, largely from their own experience, that the best initial treatment is to give 5 ml. of a 10% solution of leptazol. If there is a response to this "orientation dose" they continue with the same dose given every 10 or 15 minutes. Otherwise they give picrotoxin 25 mg. followed by 15 mg. every 15 minutes, provided of course that convulsions are avoided. In general leptazol is more likely to be effective against the rapidly acting barbiturates, and picrotoxin against the slowly acting ones. Koppanyi and Fazekas do not recommend caffeine or nikethamide. Dick [5] discusses 160 reported cases and 11 of his own, all treated with amphetamine; and he favours this analeptic, if only because it is relatively safe. The Council on Pharmacy and Chemistry of the American Medical Association [6] point out that there are deficiencies in investigations of analeptics. Indeed, the evidence for giving picrotoxin at all must be judged inadequate by modern standards; and the cumulative effect of successive doses often means that too much is given, for it has a latent period of up to 30 minutes. On the other hand, leptazol acts quickly and for a short time, and it is often given in inadequate doses.

The use of ultraviolet absorption spectrophotometry has lately provided a satisfactory method of measuring the concentration of barbiturates in body-fluids. Apart from giving much-needed data on the distribution and excretion of barbiturates, this method may facilitate both treatment and diagnosis. By providing a measure of the severity of poisoning, it should make the comparison of the results of different treatments an easier matter.[7] Alwall et al.[8] in Lund have used the method to study means of increasing the elimination of barbiturates. The rapidly acting barbiturates are of course largely destroyed in the healthy liver, but the more slowly acting ones are mainly excreted in the urine. Alwall et al. were remarkably successful in speeding the elimination of phenobarbitone in poisoned rabbits by exchange ultrafiltration and by dialysis. Forced polyuria was less effective. They applied dialysis successfully in two patients, but the full details have not yet been given. Barbiturates are distributed throughout the body-water,[9] and it is unlikely that exchange transfusion [4] can aid elimination effectively; on the other hand where dialysis with an artificial kidney is practicable recovery may probably be hastened in patients poisoned with the longer-acting members of the group. But whether the mortality-rates can be improved with dialysis or with analeptics will remain in doubt until controlled clinical trials have been carried out.

RACIAL PREJUDICE

RACIAL prejudice is a powerful disruptive social force breeding violence and harming every community it touches; and its influence is becoming increasingly apparent in many parts of the world. There is every need therefore to understand its origins, to prevent its spread, and to control its manifestations. UNESCO, as the international organisation charged with the spread of peace and goodwill through education, is trying to play its part by calling together a number of sociologists, anthropologists, and geneticists to prepare joint statements on the subject of race, setting out the scientific aspects,[10] and by publishing popular booklets to carry the facts to lay discussion-groups, school-children, and others who may benefit from this information. The latest publication is *What is Race?* [11] which explains the elements of genetics, with a wealth of attractive diagrams, and scientifically refutes some popular ideas of inheritance and the belief in a master race. The scientists answer the three basic questions Is there a pure race? Is there a superior race? and Are there unchangeable race differences? with a definite No. The word "race" is used here in the genetic sense of a group of human beings with physically inherited characteristics differentiating them from other human beings. But in everyday usage race means a good deal more; it means, for instance, the classification of man by nationality, culture, religion, colour—or the shape of his nose; and the classification may have little to do with his ancestry. If scientists restrict the word to their own use and meaning, other people will have to find another word for what is after all quite a different meaning.

[11] What is Race? Department of Mass Communication of UNESCO. 1952. Obtainable from H.M. Stationery Office. Pp. 85. 5s

UNESCO tells how an observer from Mars, the objective scientist, views the human species What we want to know is how men come to view one another as they do The fact, for example, that the relatively recent ancestors of present-day Scotsmen came from Ireland, Scandinavia, and France does not prevent Englishmen from recognising the Scots as a distinctive group (or from saying that "all Scotsmen are mean") Moreover, there are black Jews in Africa, yellow Jews in China, and every variety of white man among the Jews of Europe and America, so the "typical Jew" is different from country to country, and there can clearly be no "Jewish race" according to the canons of physical anthropology Nevertheless Jews are by and large a recognisable group of men marked by a common religion and common customs Ill-feeling towards such groups may be called racial prejudice, national prejudice, or cultural prejudice; but whatever its name it has very little to do with genetics or physical anthropology Thus we fear that the genetic approach to racial problems may do a disservice rather than a service to the cause UNESCO has at heart, because it hides the irrational basis of racial prejudice and pretends that it can be fought with scientific knowledge and reasoned argument The man who complains that all niggers smell is not interested in the scientific truth or otherwise of his statement, what he means is that he hates Negroes What has to be discovered is how he has come to feel such an emotion, and what are the circumstances which encourage its spread among his friends and neighbours

We are nearly all inclined to generalise about groups from single cases, and to view all foreigners with suspicion, even when they come from no further afield than Cornwall or Yorkshire We are prone to accept traditional judgments, like "the Irish are unreliable" or "the Italians excitable," because we believe we can recognise members of these groups at once by their speech and bearing, and often our experience bears out this belief In a few individuals this mild xenophobia becomes severe and pathological, and its origins require detailed case-histories to make them plain It is surprising how little psychiatric investigation there has been in the research on race prejudice To explain further how the virulent emotion of the few spreads at certain times and places to the whole community we must examine social conditions not only at the time of an outburst of violence but in the quiescent periods, and we must consider the reactions and motives of people who show no gross antiracial feeling as well as those of men who turn readily to lynching, the pogrom, and ritual murder Until this evidence has been collected we shall be unable to deal with racial prejudice other than empirically

HERPANGINA

FOR many years now a puzzling disease has reappeared in some areas of the United States each year during the summer or early autumn The illness, nearly always affecting children and generally those under 5 years of age, starts suddenly with fever, dysphagia, anorexia, sore throat, and pharyngitis, sometimes associated with vomiting and abdominal pain, usually it lasts 2–3 days Its most characteristic feature is the appearance in the mouth of a few greyish-white papulovesicular lesions, 1–2 mm in diameter and surrounded by an areola of erythema After 2–3 days these papules break down to give greyish-yellow ulcers which resolve after a few more days To this disease Zahowsky[1] gave the name herpangina, since it is somewhat similar to herpetic stomatitis Subsequent workers failed, however, to isolate the virus of herpes simplex The lesions in herpangina can be differentiated from those of herpetic stomatitis because they are limited to the anterior fauces, soft palate, uvula, and tonsils, while those of herpes are generally most pronounced on the buccal membrane and often associated with fœtor oris, gingival hæmorrhage and local lymphadenopathy Also herpangina occurs seasonally in small epidemics, whereas primary herpetic stomatitis is a sporadic disease rather more prominent in the winter[2]

Huebner and his colleagues[3] at Bethesda have shown that herpangina is probably the most common manifestation of infection with the A group of Coxsackie viruses In suckling mice, this group causes a diffuse myositis affecting predominantly skeletal muscles and not involving the brain, fat, or pancreas as the group-B viruses do Huebner and his associates surveyed a small community in the north west of Washington, D C, before, during, and after a small outbreak of herpangina for the presence of Coxsackie virus of the A group and for antibodies against six strains of Coxsackie virus, five of which had been isolated in cases of herpangina in this or neighbouring areas The virus was found only in those people who had herpangina or were contacts of cases and in whom antibodies to the infecting strain developed The level of antibodies to the other strains causing herpangina elsewhere remained constant in both the infected and the uninfected people The Bethesda workers also showed that the infected group had no previous antibody to the infecting strain, whereas in the non-infected group the percentage of people with neutralising antibody was very high In infected households contacts with antibody in their blood did not have the disease or harbour the virus Thus the localisation of the epidemic was apparently due to the majority of the population being immune because of previous infection, for, although coming into contact with the virus, these people were protected by their circulating antibody, which was shown to keep the same titre for at least a year So far Coxsackie virus has been isolated from either the throat-washings or the fæces of 90% of the 50 cases of herpangina investigated from 46% of contacts and from only 1% of the remainder of the population surveyed

Infection seemed to spread from case to case, the incubation period being 1–10 days Outbreaks were not explosive, as might be expected if the virus were spread by a vector such as food, drink, or infected flies. Coxsackie viruses have been isolated from flies, and Melnick and Penner[4] have shown that the virus may survive, although not multiplying, in this host for as long as 14 days So far it is not known where the virus hibernates during the winter and spring Nor is it known how long it can survive in carriers, the longest time after initial infection that it has been found is 78 days These viruses are fairly resistant, and possibly if conditions were suitable they might survive outside the body and be taken up by man or some other vector and so initiate another small outbreak if introduced into susceptible households, sporadic cases of herpangina almost certainly go unrecognised, and probably these keep the infection alive in a community

Coxsackie viruses have been associated with poliomyelitis and other diseases, but often such isolations may have been due to chance At present it seems that the commonest manifestation of infection with the group-A Coxsackie viruses is herpangina, and that perhaps the chief syndrome due to the B group is Bornholm disease either in its typical or in its more non specific form There is some evidence, however, that occasionally Bornholm disease may be caused by group A viruses also, although this disease might easily be wrongly diagnosed in cases of herpangina with abdominal pain and only a solitary lesion on the fauces influences (Bourne 1944) but it must also be remembered that the weight of the mother is in addition an index of her nutritional status. True it is usually accepted that the birth weight is only adversely affected when the mother's nutritional state is poor, but this may have been an influencing factor on the babies born in the lower-weight groups of this series. (The average weight of Sinhalese women, aged 26 to 30 years is 95·5 ± 1·23 lb., and 95 of these mothers were less than 90 lb. in weight.) Like the very undernourished mothers the very anæmic mothers (with hæmoglobin levels less than 5 g. per 100 ml.) had babies with significantly smaller birth weights. The reverse—i.e., increased birth weight after unlimited feeding during pregnancy—does not hold true, at least in rabbits (Wishart and Hammond 1933). The People's League of Health (1942) investigation, where a group of pregnant women were given supplements of iron, calcium, and vitamins A, B-complex, C, and D, also showed that these supplements did not significantly affect the birth weight.

[4] Melnick J L Penner, L R *J exp Med* 1952 96, 255

Birth weight bears a definite relation to the postnatal progress of the newborn baby. Thus, Illingworth and others (1949) have shown that in each age-group from 6·5 to 13 years children of higher birth weight are on the average significantly heavier and taller than those of lower birth weight. A similar relationship exists for the children of Ceylon, and in one group of 327 children, the weight at birth was positively correlated with the weight at 15 months (r = + 0·468), at 3 years (r = + 0·496), and at 6 years (r = + 0·423).

As birth weight is positively correlated with weight-growth during childhood, the latter will be indirectly influenced by the mother's weight and the number of her previous gestations. These again depend upon genetic and nutritional, and therefore socio-economic, factors. In other words heredity may determine the growth-potential of the individual, but the baby may yet be hampered at the outset in its chances of achieving this potential growth by malnourishment of the mother before its birth.

TABLE VIII—SIGNIFICANT VARIATIONS, WITH ECONOMIC STATUS, IN FITNESS INDICES AND RELATED ANTHROPOMETRIC CHARACTERS

Fitness index or related anthropometric character	Significant differences between income-groups
Strength, exhaustion-time, and speed	Higher > Intermediate > Low
Surface area	Higher > Intermediate > Low
Bi-iliac diameter	Higher and Intermediate > Low
Bi-zygomatic diameter.. ..	Higher > Intermediate and Low
Chest circumference/height ..	None
Leg length	Higher and Intermediate > Low
Bi-acromial diameter	Higher and Intermediate > Low
Weight	Higher > Intermediate > Low
Chest circumference	Higher and Intermediate > Low
Chest breadth	Higher > Intermediate > Low
Chest length	Higher and Intermediate > Low

Birth weight is also said to be related to the postnatal functional progress of the child (Bourne 1944). In 327 Ceylonese children the average birth weight was 6·51 ± 0·06 lb., the average age for first teething 9·5 ± 0·11 months, for first walking 12·7 ± 0·12 months, and for first talking 12·4 ± 0·14 months. By the method of least squares, it has been shown that the birth weight in this group of children was negatively correlated with walking-age (r = — 0·203, P = 0·05) but was not correlated with the teething (r = + 0·089) and talking ages (r = — 0·096). Walking-age was, however, positively correlated with talking-age (r = + 0·371, P = 0·001) and with teething-age (r = + 0·195, P = 0·05),

TABLE IX—MORBIDITY RATIOS FOR DIFFERENT CAUSES OF ILLNESS BY SEX AND FAMILY INCOMES, CEYLON, 1950

Cause of illness	Family income Rs. per month									All groups

prophylaxis for the gonococcal condition seem to me, to say the least somewhat uncertain, and, if prophylaxis is to be continued, it seems preferable to substitute penicillin for silver nitrate as you suggested.

Notification of the "sticky eye" is no doubt of little value, but notification of ophthalmia neonatorum, which includes possible cases of gonococcal ophthalmia, has evidently proved invaluable in (temporarily?) eliminating this condition. Unless we can be certain that blindness from this cause can no longer occur, notification would, like prophylactic measures, appear still to have a useful function.

London, W 1

H E HOBBS

LOCALISED MUSCULAR ATROPHY IN DIABETES

SIR,—I was interested in the article by Dr Hirson published on May 16. I was glad to read Dr Harris Jones's letter (May 30), and feel I must add my observations to his.

I entirely agree with Dr Harris Jones, for my feeling about Dr Hirson's paper was that he was, in fact describing fat atrophy rather than muscular atrophy. I have seen a number of cases where fat atrophy has occurred in areas where no insulin has ever been injected. I have never seen localised muscular atrophy associated with fat atrophy, as Dr Hirson described.

The photograph of his case 1 is very typical of fat atrophy in the arms of an old lady, and I am not convinced that it is true muscular atrophy as well. The most affected arm is the left, where the muscles are usually rather smaller than in the right. The localised patches of "atrophy" he shows in cases 5 and 6 look typically like fat atrophy, and I cannot see how there could be such a localised area of muscular atrophy in a long muscle.

I have discussed this article with my colleagues at King's College Hospital diabetic clinic, and they agree that, for the reasons given above and for those given by Dr Harris Jones, the evidence for a specific diabetic muscular atrophy is slight.

Diabetic Clinic
King's College Hospital,
London, S.E 5

JAMES A ROBERTSON

TRICHOMONAS VAGINITIS

SIR,—Concerning the correspondence on this subject, may I point out that trichomonas vaginitis in young girls is not rare in this country. In most of these cases the mother also has trichomonas vaginitis.

Tel Aviv Israel

S ROSENBAUM

THE INCONTINENT WOMAN PATIENT

SIR,—I was very interested in your annotation (May 23) on the incontinent woman patient and the use of sphagnum moss in dealing with this most distressing condition. As you say, any device which would reduce the burden of incurable incontinence is worthy of trial.

Another approach, which has been attempted from time to time, is the incorporation of a drainage system into the patient's bed. The disadvantage of such a system is that it inevitably requires a fair degree of immobility on the part of the patient. Enforced immobility is undesirable, but obviously many hopeless incontinents are also quite unable to move because of the nervous system disease or mental apathy, which is at the same time the source of their incontinence. Indeed it is almost a corollary that if mobility can be restored, incontinence will be cured.

On the basis of these facts some trials have been undertaken in Glasgow of a moulded bed with a drainage aperture and receptacle for urine and fæces. The principle of such a bed is that of the dorsal plaster shell, which not only maintains the perineum over the drainage aperture but reduces the liability to pressure-sores by distributing the patient's weight over a large area of soft tissue. Such a bed is made in sections, which can be approximated or moved apart to accommodate patients of varying heights. Adjustment of a standard mould to individual shapes is achieved by a specially prepared soft 'Dunlopillo' mattress. The bed is described elsewhere in detail.[1] Trials so far have shown that in selected cases patients can be kept dry and comfortable for longer than a year at a time. It is most satisfactory with females. In many cases they can be sat out of bed for some time each day.

At present an attempt is being made to modify this bed so that it may be used to nurse patients in an orthopnœic position while maintaining the principle of a moulded bed. If this can be achieved it should be possible to eliminate the menace of heavy patients with heart-failure and respiratory failure clambering on to bedpans.

London, W 12

JOHN C BROCKLEHURST

THE BRACHIAL-PALSY HAZARD

SIR,—I was very disappointed to read in THE LANCET of May 30 the editorial note which you saw fit to append to my letter.

The letter concerned a principle which seems to me important, and as its second sentence made clear, it used the matter of brachial-plexus injury only as an illustration. Thus your note setting out your beliefs concerning several technical procedures seems to me to obscure rather than illuminate the problem I tried to present.

A possible interpretation of your note would be that if I had been aware of the variety of prophylactic manœuvres to which you refer, I would have realised that the risk of plexus injury on the operating-table could clearly and certainly be eliminated and that I would not therefore have used this risk as an illustration. Ignorance of this variety of procedures is not the only possible explanation, however. Conviction comes to some of us more easily than others. When the complication is, in any event, unusual, it will need much more experience than has yet accumulated to allow me to follow you in describing these many prophylactic measures as successful. Meantime, whether the arm is betwixt or beyond the coronal plane I still feel justified in saying "Let us, *for argument's sake*, admit that there is a risk of brachial plexus injury following maintained abduction of the arm under anæsthesia."

It now seems to me that I owe your readers an apology. One purpose in writing my letter was to lend a grain of mutual support to those doctors who really have to deal with such conflicting risks in practice. Little did I think that I would release from your respected pen words which in a particular instance, will, I think, increase their embarrassment.

Department of Anæsthesia
Royal Victoria Infirmary,
Newcastle upon Tyne

E A PASK

⁂ An editor naturally finds it painful to see any subject discussed without mention of the many articles on it which he has recently published. Dr Pask must forgive our zeal for giving information. As for our convictions, we agree that the anæsthetist should do whatever he thinks best in the particular circumstances.—ED L

THE CORONATION

SIR,—May I congratulate you on the verse for the occasion of the Queen's Coronation in your issue of May 30? This surely must express the sentiments of thousands of her subjects. It is most felicitous. W R B has spoken well for us.

Frampton on-Severn
Gloucestershire

JOSEPH BOULTBEE

---

although the talking and the teething ages were not related significantly (r = + 0·105).

MORBIDITY

A low income is associated not only with a poor diet, poor growth, poor physique, and poor function but also with a higher incidence of disease. A morbidity survey in Ceylon (Cullumbine 1952), which collected data from 1 in every 80 families in the total population, showed that the general morbidity from all reported causes increased, for either sex, as the income fell (table IX).

As the family income fell, the incidence rose of the parasitic and infective diseases (including typhoid fever, tuberculosis of the respiratory system, malaria, "influenza," ankylostomiasis, and dysentery), diseases of the digestive system (including diarrhœa, enteritis, and ulceration of the bowel), normal and abnormal late pregnancy, childbirth, and puerperium, diseases of the blood, deficiency diseases, the rheumatic diseases (including rheumatic fever and chronic rheumatism), diseases of the skin, diseases of the eye (including conjunctivitis), infirmities such as deafness, dumbness, blindness, accidents, and senility. Most of these relationships between low-income and disease-incidence can be reasonably explained by the association of poverty with overcrowding in the homes, poor sanitation, deficient nutrition, dirt, increased hazards from heavy manual labour, and ignorance and low standards of nursing care and personal hygiene.

By contrast, as the family-income rose so also did the morbidity-rates for diseases of the circulatory system (including hypertension, pericarditis, endocarditis, myocarditis, and diseases of the coronary arteries), pleurisy, diseases of the buccal cavity, appendicitis, hernia, diseases of the genito-urinary system, abortions, and diabetes. Most of these causes are the so-called diseases of civilisation.

The intermediate-income group had the highest morbidity-rates for respiratory diseases (including bronchitis and pneumonia), indigestion or dyspepsia, and possibly hæmorrhoids and peptic ulcer.

Personal Papers

POLIOMYELITIS

I was driving home after watching the hospital rugger-team play when my attack of poliomyelitis began. I felt cold and unwell, and shortly after arriving home I had a rigor. After twenty-four hours in bed I felt almost normal but lassitude and general malaise cut short two attempts to return to work. Five days after the onset I was apparently completely recovered and resumed all my usual activities. Two days later I attended a social function with my family. My youngest daughter was overcome by shyness and insisted on my carrying her for so long that my arms and shoulders ached intolerably. I have no doubt that this episode was of importance in determining the distribution of the paralysis which was soon to follow. The same evening I noticed a trivial pain in my neck. In retrospect I do not see how the ultimate diagnosis could have been made during the minor illness.

THE MAJOR ILLNESS

The next morning I awoke with a headache and general malaise. The headache was so severe by lunch time that I retired to bed. It was predominantly occipital and accompanied by sharp pains in the neck and back of the head. There was moderate fever, but no neck stiffness, at this stage. Still, I became apprehensive, and remembering Ritchie Russell's dictum—too late as it proved—clung to my bed. The headache was intense and aggravated by coughing and straining. Vomiting began the next day, and though I only vomited four times the experience was memorable: intense and exhausting retching lasted for about a quarter of an hour and was accompanied by the involuntary swallowing of large volumes of air, which led to a most unpleasant gastric distension. On the third morning of the major illness it was suggested that I should go into hospital, but at my request the decision was deferred for a few hours. Shortly after the consultation I rose to brush my hair and found that I could not use the comb owing to weakness of my left arm and shoulder. Within a few hours I was in my own hospital having a lumbar puncture performed by my *senior registrar*. This was an entirely painless procedure.

There was no spread of the paralysis until the next afternoon, when I suddenly felt that a curtain was being drawn across my pharynx. On trying to drink I found that swallowing was extremely difficult. My voice began to weaken. At this point I was transferred to another hospital where special nursing facilities were available. The headache remained intense, and the pains which had previously been limited to my neck spread slowly down my back.

Next morning, when I found that my dysphagia had apparently become complete, I became extremely agitated; fortunately it was soon demonstrated to me that I could swallow fluids with the aid of a straw, provided I drank very slowly. My voice grew progressively feebler. Finally on the fourth day of the paralytic phase my right shoulder-girdle and arm became affected, but I was so preoccupied with my bulbar palsy that this last blow seemed unimportant.

At the end of the paralytic phase I was left with a bilateral affection of the arms and shoulder-girdles, a severe but incomplete bulbar palsy, and relatively mild involvement of the intercostals and various trunk muscles. It was surprising to discover the extent to which paralysis was perceived as a numbness or heaviness rather than weakness—a point which Gooddy has made.

THE MENTAL STATE

The mental state during the first week or ten days of the major illness was of considerable subjective interest. I felt all the time that I possessed complete insight and awareness, though in retrospect this was clearly not the case. For instance, when I first noticed the weakness in my left upper limb I returned to bed and thought hard for some twenty minutes before I was able to decide what had happened. Again, I am told that when I heard I was to be transferred to another hospital I remarked in my disappointment, "If I had not told them about my bulbar palsy they would have allowed me to stay here." Yet I was able to navigate the ambulance from a stretcher for the whole of the 7-mile journey from my home to hospital, and on my transfer to the second hospital I regaled myself and my companions by naming the various streets as we crossed London.

I was much troubled by flight of ideas: a succession of confused and unrelated thoughts sped through my mind so rapidly that I was unable to seize and hold any one of them. This experience was particularly frustrating and annoying at night, preventing any sustained thought or contemplation during many sleepless hours. Nevertheless it had its compensations, for the serious nature of my illness caused me relatively little appre-

Obituary

GEORGE SCOTT WILLIAMSON

M C, M D Edin

At the age of 69 Dr Scott Williamson died on June 4 Joint founder, with Dr Innes Pearse, of the Pioneer Health Centre at Peckham, he gained most honour outside his own profession and his own country But by any reckoning the Peckham achievement was remarkable, and no experiment that has made so many people think—and will probably set them thinking again—can be considered more than superficially a failure His last years were spent in the shadow of disappointment, but in preferring the study of health to the study of disease he had trodden a new path that may some day become a highway

He was born at Ladybank, in Fife, the son of Captain David Williamson, and was educated at Barnard Castle and Edinburgh After qualifying with the Scottish Conjoint diploma in 1907, he took up pathology and held posts at Nordrach-on-Dee Sanatorium, at the West Riding Asylum, and with the Clinical Research Association, before becoming pathologist to the Bristol General Hospital and assistant to the professor of pathology at Bristol Having taken his M B at Edinburgh in 1914, he saw service in France from 1915 to 1918, commanding the 2/3 South Midland Field Ambulance, with the rank of lieut -colonel, and winning the Military Cross After demobilisation he graduated as M D Edin, gaining the gold medal, and was appointed director of pathological studies at the London School of Medicine for Women, and pathologist to the Royal Free Hospital and the Central London Ear, Nose, and Throat Hospital He had already shown an unusually wide range of interests, writing ably on bacteriological, biochemical, and histological subjects At the Royal Free his research concentrated increasingly on the structure and function of the thyroid gland, and after retiring from his post at that hospital in 1928 he chose the thyroid and thymus glands as the subject of his investigations undertaken as first holder of the Mackenzie-Mackinnon research scholarship of the Royal Colleges of Physicians and Surgeons In 1925 he had given Arris and Gale lectures to the College of Surgeons on the anatomy and physiology of the thyroid apparatus

But Scott Williamson's major contribution to medicine arose out of work done outside working hours With Dr Innes Pearse, who had collaborated in his thyroid investigations, he began to think in larger terms of human welfare, and (unlike so many thinkers) they lost little time in putting their ideas into practice Their first centre, a club for working-class families was opened in 1926 and with this experience behind them they produced in 1931 *The Case for Action* The support that enabled them to create a big new building and organisation at Peckham was won because they had something more than a building scheme to offer they had a new message which attracted people far and wide

The medical approach, said Scott Williamson is derived from pathology—the study of what is *wrong* with people (physically mentally or socially) The Peckham approach is derived from "ethology"—the study of what is *right* with them

> "Having determined what is right you *must then proceed* to cultivate and educate or grow the *right* by *ecological* methods Just as therapy is the technological aspect of the science of pathology, so is ecology the technological aspect of the science of ethology Hitherto what is right—health or wholeness—has been assumed to be able to look after itself In fact even the proposed new medical services assume that all those who can look after themselves by whatever means are ipso facto the healthy and vital—a most disastrous error We have not only adopted, but deliberately enforced a laissez faire attitude to personal health so that any individual concerned for his own health is dubbed a *neurotic* or psychotic'
>
> The systematic study of *pathos* of the people, or pathology has proved its worth but the best that can be made of a bad job with it is to stop the bad from getting worse In the Peckham Health Centre we have begun a systematic study of the *ethos* of the people, and have made a first tentative technological approach to their ecology Health, we have discovered, is like a seed it must be sown, grown, and cultivated in the seed bed, garden, or tilled field—the homestead—of the social soil "[1]

The work at Peckham, and its philosophical basis were described in *Biologists in Search of Material* (1938), and in *The Peckham Experiment* (1943), the Pioneer Health Centre (so different in conception from the kind of health centre envisaged for the National Health Service) was filmed by the Ministry of Information and became well known abroad, and as "the first serious attempt to found sociological work upon a biological basis" the whole project was continually under discussion The advantages of periodic medical examination, on which the founders insisted, are of course a perennial subject of controversy, and this was extended to the technique of the family consultation, which put the members in possession of whatever information the centre had obtained about them But sympathisers as well as critics could not help remaining doubtful about the scientific value of the biological data to whose accumulation and analysis Scott Williamson attached so much importance; and, looked at purely as a new form of community centre, Peckham failed to justify itself by acquiring a life and vigour of its own apart from the inspiration and vigour of its founders "The centre," wrote one who had worked in it, was "lacking in an essential social activity peculiar to humans, and in this sense it was biologically inadequate to its task "[2] Many, none the less, will share the same commentator's hope that the ideas that underlie its conception "will one day be put to a searching though sympathetic test"

S T writes

Scott Williamson's dream was of a day when it would be within the power of the family doctor to create individual health rather than treat disease But his enthusiasm raced far ahead of work a day medical science So he failed to convince the age in which he lived of the validity of his message

His conviction of the need for action to raise health standards among the industrial population found practical expression in April, 1926, when the original Pioneer Health Centre was opened in a small house in Peckham It was a family club, with a subscription of 6*d* a week for the whole family In return, there were club rooms for various activities welfare clinics, an afternoon day nursery, and a compulsory annual health examination for every member The centre was, in fact a community centre, with health examinations as a pill in the sugar, and "the doctors moving freely among the people, and making observations to supplement those gathered in the consulting room' "By adjusting bad habits observed at the centre, we were able to prevent the onset of disease ' It may well have been true, indeed, I believe it was true But the evidence presented was certainly not enough to convince the scientific sceptic

On their experience, Dr Scott Williamson and Dr Pearse were soon convinced that they were on the right lines They shut down the little centre, and made preparations for something much more ambitious With great difficulty, funds were raised, and in 1935 the new Pioneer Health Centre was opened It was a striking concrete and glass building created around a magnificent swimming pool A cafeteria and a dance room overlooked the pool A pool for toddlers could be filled to any depth required There was a gymnasium a day nursery, quiet rooms and clinic rooms, and a whole suite of medical consulting rooms and laboratories Today we could take many of these facilities for granted in a community centre, though they are still rare enough To have created them by voluntary effort in the ' bad old 1930s was a *miracle*

To meet costs family membership subscription was raised to 1*s* a week With 2000 families it was calculated that it would be self supporting Yet somehow it never quite came off Income never matched expenditure and help had to be sought first from one charitable body, then from another With the war and evacuation it had to close down and weeds grew in the gardens the windows cracked, the concrete began to look very shabby Afterwards, it never got fully into its stride

The coming of the National Health Service brought no hope to the organisers of the Pioneer Health Centre It was

2 Chance M R A *Ibid* 1950, i 726

hension during these early days; it was later that I was assailed by fears, both reasonable and otherwise. This lack of concern extended to my family: I did not begin to worry about the chance of their contracting the infection until that possibility had become remote.

During this period of confusion I had fantastic day-dreams. My favourite was one in which I lay couched in my own medulla watching the outfall of nerve-cells from my nucleus ambiguus, an experience characterised by the complete absence of any affective element. For several days I was unable to appreciate the size and arrangement of my cubicle: at night, for instance, it expanded to an enormous room in a mythical "house on the South Downs," or contracted to the box-like compartment where the stable-lad sleeps at my daughters' riding-school. In the confusion resulting from this uncertainty as to my whereabouts I was prone to get out of bed at night. Even by day I was unable fully to appreciate the organisation of extrapersonal space. It was some three weeks before I was able to read with normal enjoyment, and about a month before my mental state was completely normal. Insomnia was a most unpleasant symptom. For seven to ten days I had very little sleep at all, in spite of the administration of various hypnotics. Indeed, normal sleep did not return for some six weeks.

FASCICULATION

Fasciculation appeared on the second day of the major illness, but it was not sufficiently obtrusive to warrant attention, in my case, until paralysis had actually appeared. The movements then became more widespread and of sufficient violence in one muscle at least to deserve the term myoclonus rather than fasciculation. Admittedly the fasciculation was predominantly situated in the areas which became paralysed, but it also affected parts where there was no demonstrable weakness. Moreover, the muscles in which fasciculation was most active were not those which were most severely paralysed. Fasciculation continued at a reduced rate for many weeks, and though now slight is still felt and seen six months after the onset of symptoms. I have used the term to denote spontaneous fasciculation and not the action fasciculation which has long been recognised as a phenomenon encountered in muscles partially denervated as the result of poliomyelitis.

RATE OF RECOVERY

I have been relieved to find that neuronal recovery clearly continues for much longer periods than one might imagine from a study of the literature. I suppose my bulbar palsy began to improve in ten days, but I did not derive any comfort from the degree of improvement until the fifth and sixth weeks, when there was a dramatic change for the better. The ninth and tenth weeks saw a similar rapid improvement. As late as the fifteenth week my voice made great progress quite suddenly in a matter of three days; this could only have been due to central factors. I was particularly exercised about my bulbar palsy, as I had had a patient under my care who, after bulbar poliomyelitis, had been left with a degree of dysphagia and aphonia which would have been crippling in a doctor. Consequently I did not accept the well-founded reassurance I was given as readily as I should have done. It is, of course, a commonplace that recovery of muscular power in the early months proceeds by fits and starts. The improvement in the limbs has generally followed a similar pattern, though some muscles have lagged far behind others. Generally, six months after onset, improvement is more slow and gradual, but there are still surges of returning power in the weakened muscles.

Muscular fatigability has been a prominent though variable phenomenon. On some days all exercises and activities are well carried out, on others performance is poor and fatigue develops early. These "bad" days sometimes occur spontaneously, but more often they follow an exceptionally vigorous or prolonged period of physiotherapy or some foolish physical activity on my part. The other day I was stupid enough to spend three hours gardening; it has taken several days for my muscles to return to their previous average level of performance. The fatigue is always generalised and may affect muscles which have apparently been untouched by the disease. This fatigability also affects the bulbar muscles on occasion, but it is more difficult to assess at this level.

During rehabilitation, cramps began to occur in a few muscle groups on exertion. They still persist but are lessening in severity. Apart from specific muscular fatigability, there is a troublesome and recurrent general tiredness which limits both physical and mental activity. Adequate periods of rest are required to prevent this symptom arising.

TREATMENT

Ritchie Russell has given an excellent account of the management of the patient with poliomyelitis in his recent book. He has anticipated most of the points I would have raised from the patient's point of view. Whilst supporting his teaching on the value of early active movements in rehabilitation, my own experience is that exercises should be continued to a point just short of fatigue and not beyond it; if I proceed further than this point it only means that my physical activity has to be correspondingly reduced the next day, so the net gain is nil.

The importance of the physiotherapist in treatment can hardly be over-emphasised. She requires not only a good knowledge of the anatomy of movement, and considerable intelligence, but also the ability to maintain the patient's enthusiasm by varying his exercise programmes and sparing him the boredom which follows too much repetition. If she is a good conversationalist with a wide range of interests so much the better.

There is need for an authoritative statement on safe means of sedation in bulbar poliomyelitis. I found the lack of sleep the worst feature of the acute stage. I was fortunate to have a "functional leucotomy," as my physician termed it; but for those who are less favoured prolonged sedation would clearly be a great relief. At the height of the major illness only large doses of 'Sodium amytal' were effective in my case. I did not require analgesics so long as I was nursed on a 'Sorbo' rubber or interior-spring mattress: the pains and stiffness in my neck and back rendered a hard mattress intolerable.

Ritchie Russell has emphasised the need for training nurses in the management of poliomyelitis. I was fortunate not only in my physicians but also in my nurses, who were well versed in the care of bulbar poliomyelitis. This was a considerable source of confidence to me, and one that should be available to all afflicted with the disease. It is difficult to imagine a more terrifying predicament than that of the patient with bulbar poliomyelitis who lies in the care of the ignorant, and it is to be hoped that integrated plans for medical and nursing care will soon be introduced throughout the country. The present dissolution of clinical responsibility is unsatisfactory: there seems to be no reason why the physician initially in charge of the patient should not look after him throughout the whole course of the illness, seeking such help from his colleagues as circumstances might demand. A physician with neurological training is best qualified for the task.

* * *

There are compensations for most misfortunes. My illness gave my friends and colleagues an opportunity to show me the way in which the sick should be treated. I was privileged to learn many lessons from many people. Doctoring will never be quite the same again.

not, and refused to become, a local-authority health clinic It was not a G.P health centre And it refused to regard itself as a community centre So at last it had to be disposed of

In December, 1950, it was bought by the London County Council, for the use of their educational, health, and welfare services As a condition of purchase, the L C C agreed not to use the title Peckham Health Centre or Pioneer Health Centre So today, in the Queen s Road Health Centre, Camberwell, school-children are once more using the lovely swimming-bath A day nursery is open An antenatal clinic is functioning And evening classes of all kinds are in progress In an outbuilding the L C C welfare department is running a workshop for blind people One day, it is hoped to add a G.P health centre Finally, a research programme will be begun

What went wrong ? Why did the original Pioneer Health Centre fail ? Perhaps it is that the Englishman likes to keep his community life separate from his health service Perhaps he resists unconsciously any potential medical dictator—no matter how benign—who requires him to surrender both his health and leisure And although the family is obviously enough the right unit in the home, it is not necessarily the right unit for club life The Athenæum and the Women's Institute, the dance club and the working men's club, each owe their success to the clear cuts that they make across family life

And yet, when all is said and done, the Pioneer Health Centre was a noble experiment People from all over the world came to draw inspiration from the idea it represented We can only build positive individual health on a basis of knowledge of the working of the normal human being in society Such knowledge must come from experience And such experience can only come from the study of prophylactic communities Fifty years from now, when the angularities of the prophet have been rubbed off by time, we may be ready to accept Scott Williamson s message

Dr Scott Williamson married first Nell, daughter of Captain Madden, and secondly Dr Innes Pearse

CLAUDE BLAXLAND LEVICK

O B E , M.B , Ch M Sydney, F R C P

Dr C Blaxland Levick, physician in charge of the cardiology department at St George s Hospital, London, died on May 31, at the age of 56

Dr Levick was educated at Sydney Grammar School and the University of Sydney where he held Aitken and Cooper scholarships and was awarded John West and Grahame medals He graduated M B in 1920 and CH.M. in 1922 ; and in 1923 he became a M R C.P As a postgraduate he worked in Manchester, where he was a senior house-physician at the Royal Infirmary

Coming to London, he held resident posts at St George's Hospital and at the Victoria Hospital for Children, Tite Street, before being appointed physician to outpatients at the Victoria Hospital for Children in 1925 and assistant physician to St George's Hospital in 1928 He was elected F R C P in 1934 During the late war he served in the Middle East. He was appointed O B.E in 1943 and was twice mentioned in despatches

Dr Levick's two main interests were cardiovascular disease and disease in children , and he was one of the earlier physicians to use the electrocardiograph clinically. He always remained, however, a general physician, seeing each problem against the background of the whole patient , and it was this, together with care for detail, that made him a valuable consultant

C P. P writes "I knew Blaxland Levick for the thirty years he was associated with St George's Hospital He was an excellent teacher with a precise mind, so that his students were trained to think and express themselves clearly. When he became resident assistant physician he showed that he was a first-class administrator, and this was repeatedly evident from his advice over hospital matters and in committee, and during the war with the success that came to him in his Middle East appointment

'Blaxland was a shy man, but he was the most generous and helpful of colleagues and a good friend to his juniors. In his early days at St George's he was an enthusiastic skater, and he was a keen lawn-tennis and squash player He was fond of good music and had a large collection of classical records

"He will be sadly missed by his colleagues and friends, with his sense of humour and devotion to work"

In 1934 Dr Levick married Miss Stella Kent who survives him

HUGH MORLEY OLIFF LESTER

O B E , Ph D , B Sc. Lond., M R C S

THE death of Dr H M O Lester, director of medical services in Malaya was announced at the end of last month

Dr Lester graduated B SC with first-class honours in 1922, and three years later he qualified as M R C S from St. Thomas's Hospital For a time he was a demonstrator of physiology at St Thomas's , but in 1926 he gained the diploma in tropical medicine and hygiene, and the rest of his professional life was spent overseas He graduated PH D in 1935

P A. B writes "When Dr Lester first arrived in Nigeria after his appointment to the Service, some happy chance sent him to work in the north with senior men who were studying tsetse flies and sleeping-sickness He then carried out researches comparing different strains of trypanosomes in respect of their virulence and so forth As he became more senior and his administrative gifts developed, he was put in charge of the very large Sleeping Sickness Service of Nigeria. He developed the method of mass treatment of infected people in their villages, and reduced what had been a formidable and uncontrolled epidemic to a disease of quite minor importance In the period after the war he directed the research and reclamation against the same disease in British territories in East Africa His writings on the subject were always from a broad view and with a clear and definite expression of opinion

"Towards the end of his career Lester was first of all director of medical services in Palestine at the time when the mandate terminated, and finally he held the same position in Malaya It would be difficult to say which of these two posts was the more important or the more difficult Lester had an industrious and serious nature and this tended to isolate him His treatment of others and of himself was always honest and sometimes severe He is a very great loss to the public service and to tropical preventive medicine '

REGINALD JOHN STILWELL

M R C S , J.P

R J Stilwell died at his home in Hillingdon on June 5 in his 81st year Born in 1872 he was educated at Harrow and at the Westminster Hospital and qualified in 1899 He came of a long line of Stilwells interested in the care of mild psychiatric conditions As far back as 1799 patients were first received at Moorcroft, then an extensive farm in open country For 154 years a Stilwell has been associated with Moorcroft House, which became widely known for the care and treatment of psychiatric conditions of all kinds

After working at Bethlem Royal Hospital he settled, in 1903, at Moorcroft House and remained there for fifty years Handsome in appearance and always immaculately groomed, "Reggie" possessed a charming personality which endeared him to all who were associated with him Generations of patients and their relatives will remember him with affection. Those who have worked with him in any capacity will feel his loss as if he was a brother In 1907 he married his cousin Gertrude Stilwell, whose father, Dr Henry Stilwell, was physician in charge of Moorcroft House from 1860 to 1906 All who were privileged to know Dr and Mrs Reggie will recall their charming house and their enduring devotion. Mrs Stilwell died in 1947 and there were no children

Stilwell was a man of many interests He had travelled widely, and in his youth had acquired an unusual knowledge of the old masters of the Italian school of painting He was a good tennis-player and a devotee of cricket, seldom missing an important match at Lord's, and being for many years a member of the M.C C He took an active interest in farming, and the attractive herd to be seen on the home farm of Moorcroft House was evidence of his knowledge and skill He was a Justice of the Peace for Middlesex and most regular and punctual in his attendance at the Uxbridge Magistrates' Court

Medical Congresses

FERTILITY AND STERILITY

THE First World Congress on Fertility and Sterility, sponsored by the International Fertility Association and by the American Society for the Study of Sterility, was held in New York City from May 25 to 31, and combined the first congress of the former association with the ninth of the latter. The scientific programme was covered in five days and involved twenty-four sections; more than one hundred and fifty papers were read. Over 1100 registrants, representing fifty-three countries, were in attendance.

Ovulation in Hirsute Amenorrhœic Women

R. G. **Greenblatt** (Augusta, Georgia) discussed a group of 27 women who had prolonged administration of cortisone. The drug may modify the rate of bodily hair growth. Of patients with menstrual disorders, some may respond by cyclic ovulatory menses and ultimate conception, and others simply by an increased number of menstrual periods, many of which may be anovulatory; others again may show no improvement. In the hirsute female cortisone may act not merely by depressing 17-ketosteroid excretion through its inhibition of corticotrophin (A.C.T.H.) production, but by a balancing action on growth hormone and adrenal steroids which leads to a more orderly release of pituitary gonadotropins.

Respiratory Physiology and Ovulation

W. T. **Pommerenke**, R. L. **Goodland**, and J. G. **Reynolds** (Rochester, N.Y.) investigated the effects in men of injections of progesterone and œstradiol benzoate, alone and in various combinations, on basal metabolic rate, alveolar carbon dioxide tension, basal body-temperature, and serum-sodium and serum-chloride concentrations. Progesterone caused a significant increase in basal body-temperature and a decrease in alveolar pCO_2. It seemingly produced a rise in the basal metabolic rate, and an increase in serum concentrations of both sodium and chloride. A significant increase in serum-sodium and a decrease in serum-chloride was noted following œstrogen administration. The thermogenic effect of progesterone was diminished when œstradiol benzoate was simultaneously administered. The suppression of alveolar pCO_2 by progesterone was prolonged when œstrogen was also injected. Under these conditions both serum-sodium and serum-chloride levels appeared to be lowered. Studies of electrolytes and respiratory gases may be employed as substitutes or supplements to morphological criteria of œstrogen and/or progesterone activity.

Genital Tuberculosis in Sterile Women

I. **Halbrecht** (Hadera, Israel) stated that he found tubercle bacilli by means of cultures of the menstrual and intermenstrual cervical and vaginal discharges in 60 women with primary sterility, in whom tubercle bacilli were being discharged continuously or intermittently from the genital organs. In 32 of these 60 women the diagnosis of genital tuberculosis was first established by endometrial biopsies and later confirmed by the cultures of the uterine discharges. In 22 cases genital tuberculosis was detected only by cultures of the menstrual discharges, whereas the endometrial biopsies were negative. The relatively great number of cases in which tubercle bacilli were found growing in cultures of the menstrual discharges and in the cultures of the intermenstrual, cervical, and vaginal secretions, while endometrial biopsies gave negative results, enhances the value of these cultures as a factor in diagnosing latent genital tuberculosis in its earliest stages, when the disease is still limited to the fallopian tubes.

Pre-adolescent Hypogonadism

C. W. **Charny**, A. S. **Conston**, and D. S. **Meranze** (Philadelphia, Pa.) described 3 cases which were suspected to be of mild hypogonadism when first examined. Follow-up study by means of testicular biopsies revealed the progressive pathological changes leading to the adult infertile state. A constant feature is the lack of uniformit of the histological picture: relatively healthy seminiferous tubules may be seen next to tubules which hav been irreversibly damaged.

Time of Ovulation

C. G. **Hartman** (Raritan, N.J.) said that inspection c the ovary at laparotomy will often provide useful information about the time of ovulation; but in his opinion i is impossible to estimate with any precision when a give follicle will rupture. Observation of hundreds of monke ovaries, when the exact day of ovulation was know made him doubt the accuracy of estimating the ag even of "newly ruptured" follicles.

Ovulation Timing

H. **Knaus** (Vienna) described his early work o uterine muscle contractility, when he found that huma uterine muscle is controlled by the hormone of the corpu luteum in the same way as it is controlled in the rabbit Ovulation in women normally takes place on the 15t day before the onset of menstruation. In a woman wit a cycle varying from 26 to 30 days, ovulation will occu between the 12th and 16th day of the cycle, but whe the cycle is one of 21–24 days it will occur between th 7th and 10th days. The "safe period" as a method o birth-control has confirmed the practical validity of thi view of the determination of the time of ovulation.

Outcome of Pregnancy

G. I. M. **Swyer** (London) presented data on the outcom of 220 pregnancies in 207 patients, attending the fertilit clinic at University College Hospital, London. There wer 19·1% of abortions and 3 ectopic gestations. Labour wa normal in 123 patients. There were 15·4% of forcep deliveries, 5·7% of cæsarean sections, and 4·6% of breec presentations. The total fœtal-mortality and congenital malformation rates were 0·57%. Toxæmia occurred i 11·4% of pregnancies.

Peritoneal Factor in Sterility

E. G. **Murray** (Buenos Aires, Argentina) stated that alterations of the pelvic peritoneum near the tubal ovarian junction are an important cause of sterility Their frequency is 11·6% (234 cases in 2017 patients). The peritoneal disturbances were grouped as morphological and functional. The morphological changes consist of ovarian blockage (intrinsic or extrinsic), tubal blockage, blockage of the tubal-ovarian junction (simple or in pockets), and combined blockage. In functional blockage ovular migration is disturbed even in the absence of morphological changes. Diagnosis may be difficult, and often has to be based on auxiliary diagnostic aids, such as radiology. The treatment has two important stages: firstly, prophylaxis; and secondly, treatment of the pelvic blockage—the purpose being to prevent or cure the peritoneal cicatrisation and the resulting retractions. In prophylaxis the best results have been obtained with local intra-uterine or peritoneal penicillin. In rats abnormal cicatrisation has been reduced by administration of cortisone and corticotrophin. In women their use is still in an experimental stage.

Non-surgical Treatment of Tuberculosis

T. **Barns** and **Linton Snaith** (Newcastle upon Tyne) gave a preliminary report on the response to isoniazid of 43 cases of pelvic tuberculosis.[1] These 43 cases with endometrial tuberculosis, of which 3 had also infection of the cervix, were treated with isoniazid, after preliminary confirmation of the diagnosis by biopsy, animal inoculation, and culture: in all cases where typing was possible

---

[1] Barns, T., Smith, H.G.M., Snaith, L.M. *Lancet*, April 25, 1953, p. 817.

His experience of clinical psychiatry was extensive and his opinion always worth having Colleagues have often expressed their indebtedness to a quiet hint, modestly expressed, regarding the treatment of a difficult case His management of the truly objectionable patient sometimes met with in psychiatric practice was instinctively successful and the admiration and envy of the beginner

In Reggie Stilwell psychiatry has lost a senior practitioner of great distinction and charm It is sad indeed to think that he is the last doctor in a family which has done so much for the enlightened care of psychiatric illness

Notes and News

DEVELOPMENT OF ENDOCRINOLOGY

Now in its seventh year, the section of endocrinology of the Royal Society of Medicine held its first dinner on June 4, to celebrate the Coronation

Lord Horder, the chief guest, said that it seemed odd that a long struggle had been needed to get endocrinology put on the map as a section of the society It had been feared that the proposed new section would split the subject of Medicine into watertight compartments, and also that the other sections would be denuded of much of their subject matter At this distance of time, however, the objections sounded quite medieval "Some of you," Lord Horder continued, "have visions of a body, organisation, institute—call it what you will—which might place endocrinology on a still higher footing in the hierarchy of Medicine than it now occupies as a section of the Royal Society of Medicine The subject has made such strides, it has demonstrated so fully the depth and breadth of its penetration into the pathogenesis of disease, that it surely cries out for a special hospital with its attached research department As an interested outsider I would strongly support such a scheme" The progress of endocrinology had made us all breathless—or would do so if we did not exercise control The patient (impatient because human) needed protection from his credulity , the chemist must not be allowed to dictate to the clinician about the use of the substances he produced , and we must check the tendency to divorce endocrinology from general medicine He agreed with Dr S Leonard Simpson, president of the section, that while every general physician must have a good working knowledge of endocrinology this did not exclude the need for collaboration and consultation with the endocrinologist—though the latter, in his turn, must avoid taking over departments of Medicine as his special field because hormone therapy played an important part in them There was no ceiling to the reach and grasp of this branch of Medicine it began at the start of life, and it pursued life through growth, puberty, adolescence, maturity, to old age "Use your influence," Lord Horder concluded, "to get the basic and established facts of your specialty interwoven with the student's curriculum Then teach them to the practitioner"

Mr L R Broster, first president of the section, said that its strength resided in its application of applied sciences It worked in closest harmony with the Society of Endocrinology, and the collaboration between clinician and scientist was enabling them to understand each other s problems The future rested on the foundation of some institution where it would be possible to coördinate all these aspects Meanwhile, at a time when Medicine was disintegrated by splintering, the section of endocrinology was doing much to bring its parts together , for it had proved a meeting ground for surgeons, physicians, psychologists, biochemists, medicolegal experts, and many more

Dr Leonard Simpson, who presided proposed The Guests , and Dr F M R Walshe, F R S , president of the Royal Society of Medicine, reflecting the faint uneasiness of those who dine under the diagnostic eye of psychiatrists or endocrinologists, replied "on behalf of my fellow syndromes"

MEDICINE UNDER THREE QUEENS

On June 5 Sir Zachary Cope opened a new exhibition at the Wellcome Historical Medical Museum, 28, Portman Square, London, W 1

Dr E Ashworth Underwood, director of the museum, explained that the exhibition was designed as a tribute to the Queen on her Coronation, and its theme was a comparison of the state of medicine in the reigns of Elizabeth I, Anne, and Victoria The real beginnings of British medicine were undoubtedly in the reign of Elizabeth I, but compared with the Continent, England in those days was backward in the art and practice of medicine The Elizabethan age was characterised by buccaneers and a spirit of adventure, finding their expression in medicine in the heroic surgery of William Clowes (1544–1604) But by the time of Queen Anne, English medicine was represented by great physicians such as Richard Mead, John Radcliffe, and Hans Sloane During the long Victorian era, there were numerous discoveries, but only a few of the discoverers could be mentioned in the exhibition

Sir Zachary Cope began by paying a tribute to the Wellcome Trustees for their foresight and wisdom in providing and maintaining a historical museum and library of such excel the organism was of human type. Only 2 patients, with massive caseation, did not respond; 40 cases showed no infection after treatment, and 1 became pregnant. These workers are sceptical about the permanence of apparent cure, since a caseating focus elsewhere, especially in the fallopian tube, may be resistant to the antibiotic and may reinfect the endometrium.

Uterotubal Insufflation

I. C. Rubin (New York City) declared that the value of uterotubal insufflation in tubal occlusion encountered in hydrosalpinx, clubbed fimbrial ends, or atresia of the tubal lumen is purely diagnostic. Its therapeutic value is restricted to certain degrees of tubal obstruction produced by mild to moderate mucosal agglutination, perifimbrial adhesions, and tubal kinks which are amenable to improvement by repeated insufflation. In the last analysis tubal obstruction refers to barriers which block the normal passage of the ovum through the tubal lumen into the uterus. The degree of luminal constriction can be estimated by the pressures obtained during kymographic uterotubal insufflation, which are correlated with the diameter of the ovum. If these pressure-levels can be reduced to 100 mm. Hg or below, intra-uterine pregnancy can be expected. When the pressure-levels remain higher than 150 mm. Hg, tubal pregnancy is more likely. Pressure-levels persistently above 200 mm. Hg are incompatible with conception, because the lumen of the corresponding fallopian tubes requiring these high pressures is too narrow for the free transport of the ovum. Tubal obstruction refers to the blocked passage of the ovum and not to the failure of CO_2 gas or radio-opaque liquids to escape under pressure from the fallopian tubes into the peritoneal cavity. Kymographic uterotubal insufflation is very suitable for the determination of the calibre of the lumen, which is correlated with intratubal pressures. A significant difference was noted in the percentage of pregnancies following uterotubal insufflation demonstrating tubal strictures and the percentage following the test demonstrating normal tubal patency. There were, for example, 118 (31%) out of 379 patients with tubal strictures who became pregnant, as against 316 (26%) out of 1210 with normal tubal patency who became pregnant. The therapeutic value of uterotubal insufflation in cases of tubal stricture appears to be appreciable. Chance and coincidence may play their part in this treatment as in all other forms of therapy; but, after subjecting the data to the strictest criteria, it seems justifiable to conclude that uterotubal insufflation exerts a therapeutic effect in sterile women whose fallopian tubes obstruct the ovum; the obstruction is improved by repeated insufflations, and conception ensues the same month or shortly thereafter.

Ovulation Around the Menopause

A. Sharman (Glasgow) stated that the modern literature on pregnancy records no parturition after the age of 52 years. An investigation was made into ovulation, using the histological method, in 249 women 40 or more years of age. The oldest age at which ovulation was detected was 52 years: this occurred in 5 cases. In no case was secretory endometrium obtained more than ten days before a menstrual period. Ovulation dissociated from menstruation was detected in 2 women, aged 47 and 49 years. In the age-group 40–45 years, 19 out of 76 biopsies performed within ten days of a supervening menstruation revealed anovular cycles. In a group of women aged over 45 years, of 15 premenstrual biopsies 6 revealed anovular cycles. In 12 out of 49 biopsies after irradiation no endometrium could be obtained; and none of the other 37 specimens showed a secretory pattern.

Tubo-ovarian Physiology

A. Westman (Stockholm, Sweden) studied the tubo-ovarian physiology in rabbits through an abdominal window and in *Macacus rhesus* monkeys by aid of a laparoscope. During ovulation strong contractions were observed in the tubal wall, producing suction into the tube. The fimbrial apparatus swayed to and fro over the surface of the ovary, which slowly rotated round its longitudinal axis, presenting its medial or its lateral surface to the ostium of the tube. By this device the ovum is directly sucked from ruptured follicles into the fallopian tube. Some observations on radiographs gave indirect evidence of the same mechanism in human beings.

Ovulation after Ectopic Pregnancy

A. M. Siegler (New York City) studied 27 patients after operation for tubal pregnancy. A normal, ovular menstrual cycle is immediately re-established after operation.

The conference concluded with a banquet, at which it was announced that the next world congress of the International Fertility Association will be held in Italy in 1956.

Public Health

Recruits to the Local Health Services

In his report for 1952, Dr. I. A. G. MacQueen, medical officer of health for Aberdeen, says that there are grave and increasing shortages of nurses, dentists, and doctors in the local authority services. He attributes the situation mainly to the financial disparities between these members of the service and their opposite numbers in other branches of the National Health Service. He points out that the nurse who undertakes additional full-time study to secure the health visitor's certificate is rewarded by a salary which is less than she would have received had she remained a ward sister without the certificate; and there are comparable differences in the case of medical officers. Dr. MacQueen concludes: " It is obvious that, unless both the quality and the quantity of recruits to the local health authority service improve, the preventive health services will inevitably decline, as they are already doing in some places . . ."

Medical Statistics for 1948 and 1949

The medical text of the Registrar-General's Statistical Review of England and Wales for 1948 and 1949 is published this week.[1] It is primarily a commentary on the mortality and notification statistics for these years; and many of the figures it deals with have been published previously in part I of the statistical reviews for 1948 and 1949. Separate volumes giving some results of morbidity inquiries will be published as supplements to the review for 1949.

* Not including late returns.

lence both were at the service of the medical historian, and deserved to be better known because of the unfailing courtesy and erudition of those in charge of them

Before the days of Elizabeth I men had ideas about medicine but there were no facts Progress dated from the time when practitioners of the art decided to collect facts The whole of modern medicine was based on the facts of anatomy and physiology, both of which subjects, so far as England was concerned, saw their beginnings in the days of Elizabeth When she was 10 years old, Andreas Vesalius in Padua wrote his famous work on anatomy, and in 1578, when she had been on the throne for twenty years, William Harvey was born Most great thoughts had come to men in their twenties and there could be little doubt that it was during the reign of Elizabeth that Harvey first theorised on the circulation of the blood And so one could say that it was in her reign that anatomy was fertilised by physiology and modern medicine was conceived

After the important episode of its conception, the embryo entered upon rather a long period of gestation The quickening was in the reign of Queen Anne, for it was then that the first serious medical teaching was undertaken William Cheselden, produced his syllabus of anatomical lectures within a year of completing his own studies in 1710, and with Francis Hauksbee, a physiologist, as his partner he provided the first attempt at systematic medical education in this country Then came William Hunter, who founded his school of anatomy and was joined by his brother, John By the end of the 18th century there were many efficient private schools of anatomy and medicine The same century, following a lead given in the reign of Queen Anne, saw the foundation of many of our great hospitals, which provided the clinical material for the teachers Inevitably medical schools became attached to hospitals

The period of gestation of modern medicine was almost terminated by a pseudo labour in 1815, when the Apothecaries Act was passed and the first attempt made to secure a proper standard of professional skill The Act was, however, not sufficiently comprehensive, and there was no agreed minimal standard of competence for all medical practitioners until the passing of the Medical Act in 1858 and the formation of the General Medical Council That year, Sir Zachary regarded as signalising the true birth of modern medicine It was a memorable year in medicine, for Virchow was publishing his famous work on cellular pathology, Pasteur was working on fermentation, and Florence Nightingale was crystallising her ideas on nursing About this time, too, anæsthetics were being tried and the first practical applications were being made in surgery of Pasteur's important discoveries "Yes," he said, "it was a long period of gestation—from the birth of Harvey to the passing of the Medical Act was 280 years Interesting, isn't it, because it was almost for medicine in years what it is for a human being in days"

From the time of the passing of the Medical Act until now, the baby had grown, through childhood and adolescence, into manhood For the first fifty years the child was most of the time with his mother, anatomy, it was only during the present century, when he had come under the influence of his father, physiology, that real growth and development had taken place Sir Zachary concluded "Now is a time of great promise—big developments are pending I know it from reading the journals, although I do not always understand what it is all about"

After Sir Gordon Gordon-Taylor, seconded by Sir Allen Daley, had proposed a vote of thanks to Sir Zachary, the party viewed the exhibition, for help in the preparation of which Dr Underwood had expressed his thanks to Miss M E Rowbottom and to the technical staff It contains a variety of instruments of ages past, including a beautiful set of surgical knives and a miniature axe, the purpose of which is obscure they date from 1570 and were formerly the property of General William Earle Bulwer of Heydon Hall, father of Lord Lytton Among other instruments are bullet extractors of the late 16th century, spearhead removers, Savigny's syringe for blood transfusion using Blundell's technique (1818), a portable leech jar, Messrs Kidstone's 1850 novelty of the mechanical leech, an intriguing miniature stethoscope to fit snugly into the hat, and the prototype of Mackenzie's polygraph Queen Anne it seems, when touching for the King's Evil, objected (and rightly) to touching the scrofulous ulcers, so she carried a lodestone for the purpose she later presented it to John Rooper, her deputy cofferer, in whose family it remained until presented to the Wellcome Museum Also associated with the King's Evil are two examples of Queen Elizabeth's "gold angels" There is on view, too, a handsome alembic of green glass, and also one of John Marshall's compound microscopes complete with a fine adjustment screw, which were being made in 1688 There are many striking photographs of Victorian doctors, and a series of contemporary prints are set up to illustrate the many social evils which encouraged the dissemination of disease in the 1840s and 1850s The exhibition also includes numerous prints and engravings, some of which are scarce and illustrate the beginnings of English engraving Of particular interest is the handsomely rubricated and illuminated manuscript on vellum of Pierre Boaistuau's *Histoire Prodigieuses* which, following a visit to England in 1559, he dedicated to Queen Elizabeth It seems likely that the dedication was rejected, for the book was published in Paris in 1560 That the evils which the Act of 1858 eventually eradicated troubled the legitimate members of the medical profession three centuries earlier is evidenced by a copy of John Halle's (1529 ?–66) *An historicall expostulation against the beastlie abusers, both of chyrurgerie and physyke in our time*, published in London in 1565

The exhibition remains open for several weeks (Mondays to Saturdays 10 A M to 5 P M)

A FILM ON DEXTRAN

A NEW thirty minute sound and colour film, *Dextran*, deals with the theory of shock, the history of plasma substitutes, the manufacture of narrow fraction dextran, and its use in surgery It was made by Dr Brian Stanford in collaboration with Prof A M Boyd at the Victoria Hospital, Manchester, for Benger Laboratories Ltd The colour photography is superb In the operation sequence at the end of the film, the stages of a difficult operation are correlated with the patient's response on a Nosworthy chart while the blood-pressure is maintained by regulating the rate of a dextran drip But the animated diagrams, used to explain the behaviour and fate in the body of different sizes of substitute colloids could have been clearer, and, with the exception of the operation sequence, the clinical aspects of shock are omitted The emphasis of the film is on the commercial preparation of a particular plasma substitute, and a large section is devoted to factory and laboratory scenes during the production and investigation of narrow fraction dextran, with only a brief reference to its use in a case of shock The film will be useful for medical societies, but it is unlikely to be used much for teaching purposes in its entirety, though parts of it, if available separately, would be valuable to pharmacists, medical students, surgeons, and anæsthetists

NEW ZEALAND HOSPITALS INQUIRY

A CONSULTATIVE committee has been set up to advise the government on the best way of administering the New Zealand hospital system, and the other services provided by hospital boards The following have been appointed members Mr H E Barrowclough (Auckland), Dr D S Wylie (Tauranga), Dr P P Lynch (Wellington), Mr H W Shove (Auckland), Mr C A Campion (Ashburton), and Mr H S Williams (Christchurch)

This committee has been set up at a time when local rating is about to disappear from hospital finance, with assumption by the government of full responsibility The system of thirty seven local hospital boards will thus become an anachronism Discussions have already taken place between the minister, the Hospital Boards' Association, and others about regionalisation and the issue of block grants to larger regional boards The constitution of boards will have to be reviewed, at present all members are elected by popular vote The position of the health department will also be studied, it now shares with the local boards the responsibility for hospital planning and provision

---

University of London

On Nov 27, the honorary degree of D SC will be conferred on Dr H E Sigerist

Faculty of Radiologists

The following have passed the examination for fellowship of the faculty

Radiodiagnosis—D Lloyd Dick, D E Fletcher, P F New, J N Pattinson, E G Redman T R Riley, D Stenhouse, J Sutcliffe, D Sutton C K Warrick

Radiotherapy—J Boland, Mary Douglas, W B Lawson, J A Orr

In England Now

A Running Commentary by Peripatetic Correspondents

ALTHOUGH they are both more than twice my age, I established a firm friendship with Mr. and Mrs. Broadbridge soon after they moved here several years ago. Mr. Broadbridge found that he and I hold similar religious views, and he was delighted to lend me various aged books, his dearest treasures, written, as he said, by very clever men, who made short work of religions and superstitions. During our acquaintance this delightful old couple have several times peered into death's door, but have decided not to go in. Last winter they were obliged to take to the same bed at the same time, where they lay, blue and panting. I stood by and administered various medicaments, which I am sure were without effect, but for which they gasped out their unlimited thanks through cyanosed lips. Thanks, presumably, to a merciful providence that looks after these charming old heathens, they have always slowly recovered.

Mr. Broadbridge's zest for life is enormous. He is a great gardener, the best player in his bowls club, and an expert at draughts. But his chief joy is the horses, and however blue and dyspnœic he may be, he never ceases to study form. He came to see me last Friday; we exchanged a few conventional expressions of regret that the Coronation was a religious ceremony, and we were briefly indignant at the use of the title Doctor by Anglican bishops. Mr. Broadbridge then said that in the morning he would know the winner of the next day's big race, and that he would let me have it, but I must keep it under my hat. I thanked him, promised I would, and forgot all about it. Not so Mr. Broadbridge, who dragged his dyspnœic old frame to my house on Saturday morning and personally handed me a letter which was addressed to me and marked "Private and confidential." The letter read:

June 6, 1953.

Dear Doctor,
As promised I have sent the winner of the Derby.
Pinza it is.
There is no bunk about this.
Get on. Price will be short—about 9-2. But little fish are sweet.

Yours with compliments,
P. E. BROADBRIDGE.

I dare not tell Mr. Broadbridge that his efforts on my behalf were in vain. Until I had his letter I did not know what the big race was, and I have no idea of how to put money on a horse.

* * *

A strong case could be made out for strangling us amateur actors, if not at birth, at any rate as soon as we show histrionic stigmata. The plea that we get a lot of fun out of it and harm nobody is at once specious and unsound; it argues an unpardonable indifference to the sufferings of our audiences who are expected to pay good money for the dubious privilege of sitting for hours on chairs uncomfortably hard, in a hall uncomfortably hot (or cold) and deficient in emergency exists, with nothing better to do than to watch us act.

Closeted thus, and (as we insist) in darkness, they can neither read nor knit; they must merely endure. If they refuse to support us, we dub them stuffy and unsporting. If they come, we demand their attention during the performance and their adulation afterwards, sometimes even to the extent of providing bouquets or chocolates for all the ladies of the company and perhaps a box of cigars for the producer. Respites are few, for no sooner do we complete a mercifully brief run than we go into rehearsal for the next production.

At a recent performance inflicted on a sanatorium last week not only were the convalescents herded into the hall by the staff, probably armed with knouts, but the show was relayed to the wards where, it may be suspected, the more serious cases were chained to their beds with headphones clamped to their ears.

If we amateur players are to escape the violent deaths we so richly deserve, surely some compromise is possible? Might we not, for example, be allowed to act only in camera? If nobody saw us at it there might be less cause for shame. Incidentally, the same might apply to some professionals.

* * *

It isn't really too bad being a pathologist. And when I say pathologist, I mean what they do in Edinburgh—a thoroughbred morbid anatomist and histologist.

The pathologist's apprenticeship is long and hard. You are blooded in the deadhouse, whence you graduate to biopsies, and if you manage to avoid pricking your finger, you become, when bald or greying, an authority. As such, your function is to pronounce upon the difficult section. The difficult section may originate anywhere in the region; born in obscurity, it travels by devious routes, pausing here and there at conferences and laboratory meetings, and finally comes to rest on your bench when you are out for lunch. It always consists of innumerable small round cells of a nondescript type, and though recognisable tissues, varying from case to case, may be present, the Thing Itself is as clueless and inscrutable as the Sphinx. Pictures of it are common in the journals, where it is variously described as sarcoma, carcinoma, blastoma, reticulosis, hyperplasia, a peculiar inflammatory reaction, or an atypical this or that. If you send it to a panel of experts, they will suggest all these possibilities, though perhaps in a different order. The correct diagnosis is of course *incognoma* or *incognitis* (whichever you prefer). In my report I explain this in simple language, and—as requested—enclose a modest bill, but I can't remember ever being paid for my candour.

* * *

Well, the Coronation is over and as far as we can tell the hundred thousand who slept on the pavements and the thousands who got chilled in the stands seem to have thriven on it. I don't know how it all worked. Colds, we are taught, come through contact of a susceptible person with a subject who is already infected, or, as the lay person prefers it, through sitting on cold stones, leaving off winter pants, standing in the draught, getting wet feet, and the like. But witness my spinster patient who always gargles with salt and water before venturing into the germ-infested atmosphere of my waiting-room. Sustained only by swigs of brandy and the excitement of the occasion she sat for twelve hours in a draughty stand wringing the water from her clothing and enjoying it all to the full. And then there was my P.A. case with her thyrotoxic daughter. They stood for fourteen hours in Oxford Street enjoying a good view of the whole proceedings. Three others of my patients staked their claim on a patch of pavement fully twenty-four hours before the procession was due and saw everything in cold and discomfort, and loved it all. None of these have been laid low by a chill, and yet how often in the past have I treated them for colds caught through leaving off winter woollies just a few hours too soon.

It all goes to show; but what it shows I don't know, except perhaps the power of mind over matter and the fact that it takes a Coronation and a wet one at that to demonstrate this to perfection.

* * *

Every medical school has its human landmarks, comfortingly immutable in a changing world. Thus when Queen's men meet their first question is likely to be: "How is Sister Dynes?"; for Sister Dynes (her Christian name is Catherine, though this is unknown even to some of her friends) has been night superintendent at the Royal Victoria Hospital, Belfast, since December, 1909. In these forty-four years she has never been absent through illness; and during her early days, when the hospital was in financial difficulties, she might have no night off for weeks on end while an assistant was on holiday. To her work she has brought not only skill but an uncanny knack of arriving, without being summoned, at the place where she is needed; and many hundreds of ill patients have been the better for her humane attention. The not so ill—those who sought to use the hospital for bed and breakfast—could be spotted by their whispered: "Is Sister Dynes on tonight?" It is only some of these who will not share the general pleasure at the appointment of Sister Dynes as M.B.E. in the Coronation Honours list.

Royal College of Physicians of Ireland

The following have been admitted to fellowship of the college

George Gregg R H O'Hanlon R W M Strain P J Sweeney, W D Hughes, Muhammad Aslam Pirzada (in absentia)

The following have been admitted to *membership*

J P A Ryan J D Sullivan

Society of Apothecaries of London

The following candidates have been granted the diploma of the society (L M S S A Lond), enabling them (upon complying with the requirements of the Medical Acts) to practise medicine, surgery, and midwifery

A Booth, G I Taylor, H A Whitehouse, G J John, J G Cooper, V R Jones R G Jones G R. Vesey, C M Stevenson, J D Spouge, J W S Webb, D J Waller G L Haworth, L Chapman, C L Smith, W G Rhys Jones, D Porter E W Fowler, T C Ryan, E R Lester, E McK Sycamore, R A Cooper, W G Nethery, B Lewis, and J A Scanlon

Members of the livery are summoned to attend at Guildhall at 11 45 A M on Wednesday, June 24, for the election of sheriffs and other City officers annually chosen on Midsummer Day

West London Medico-Chirurgical Society

The society's annual banquet is to be held on Thursday, June 25, at 7 30 P M, at the Apothecaries' Hall, Blackfriars Lane, E C 4

National Smoke Abatement Society

A proposal to form a south east divisional council will be considered at a meeting to be held at Caxton Hall, London, S W 1, at 2 30 P M on Friday, June 26 Dr A J Shinnie, medical officer of health for Westminster, and Sir Ernest Smith, D SC, will open a discussion on pollution problems in this division

Princess Tsahai Hospital

A general meeting of subscribers to this hospital's Fund is to be held on Tuesday, July 7, at 3 P M, at Tuke Hall, Bedford College, Regents Park, London This meeting, at which a film of the opening of the hospital will be shown, is to be followed by a garden party The hon secretary is Miss Sylvia Pankhurst, 3, Charteris Road, Woodford Green, Essex

South African College of Physicians and Surgeons

A College of Physicians and Surgeons may be established in South Africa before the end of the year The new college would enable South African doctors to take higher qualifications without leaving established practices to go overseas In an editorial the *South African Medical Journal* says that the founding of the college would be one of the major achievements of the South African Medical Association and one which would have far reaching effects on the quality of medical practice in the Union

Westminster Hospital

The annual dinner of old students was held in a happy pre Coronation atmosphere on May 29 The toast of The Hospital and Medical School was proposed by the chairman, Dr I W Magill, in a single sentence Mr H E Harding, the dean, admitted that such brevity caught him a little unprepared, but went on with customary ease and wit to welcome The Guests each as an old friend In reply, Sir Robert Young spoke of the phenomenal advances in medicine he had witnessed In his early days there were no X rays and the clinical laboratory was only just being established There was thus far less help and more uncertainty, but much more thrill in being right In anæsthesia the contrast between the days of Clover's inhaler and the present time was very great and he had much admired the contributions of Dr Magill to this change But, although science must play its part, he hoped the *art of medicine* would not be neglected, and most of all that the real flower of the profession—the general practitioner with his knowledge and interest in personality—would be restored to his rightful position in the family of his patients Dr Robert Machray, in proposing The Chairman, voiced the regret of all on Dr Magill's impending retirement after 29 years on the honorary staff Responding Dr Magill said that intubation had become commonplace and was taken for granted by the young anæsthetist and surgeon who now had relaxants, a bloodless field, and perhaps refrigeration in the offing He would warn both however against placing too much reliance on resuscitation or using sledge hammer methods in anæsthesia as a cover for lack of gentleness in surgery

Osler Club of London

At a meeting to be held at 1, Wimpole Street, W 1, on Friday, June 19, at 7 45 P M, Mr A Dickson Wright will speak on Some Royal Case Histories

Electronics Exhibition

The 8th annual exhibition of the north western branch of the Institution of Electronics is to be held at the College of Technology, Manchester, from July 15 to 21 The exhibition, which will be opened by Sir Geoffrey Jefferson, F R S, will include displays of the medical applications of electronics

Royal Society of Tropical Medicine and Hygiene

At the annual general meeting of this society, to be held at 26, Portland Place, London, W 1, on Thursday, June 18, Sir Neil Hamilton Fairley, F R S, the retiring president, will induct Dr F Norman White as president for 1953–54

Welsh National School of Medicine

Dr A S Duncan has been appointed the first whole time professor of obstetrics and gynæcology in the school He will succeed Prof G I Strachan, who retires on Oct 1

Dr Duncan, who is at present senior lecturer in obstetrics and gynæcology at the University of Edinburgh, graduated M B Edin in 1936 He took the F R C S E three years later and the M R C O G in 1941 During the late war he served as a medical officer in the Royal Naval Volunteer Reserve and he was awarded the D S C in 1943 In 1946 he was appointed lecturer in obstetrics and gynæcology at the University of Aberdeen, a post he held till he took up his present appointment in 1950 He was one of the authors of a *Combined Textbook of Obstetrics and Gynæcology* (1950), and he has also contributed chapters to the *Encyclopædia of Medical Practice* (1951), and to *British Gynæcological Practice* (1952)

World Health Organisation

At the meeting of the executive board in Geneva on May 28, Dr Melville Mackenzie, a principal medical officer of the Ministry of Health was elected chairman of the board The board decided that the topic for the technical discussions to be held at the Seventh World Health Assembly next year will be Public Health Problems in Rural Areas—a subject proposed by the Yugoslav delegation at the sixth assembly, which has just ended in Geneva The director general of W H O was asked to study with the International Labour Organisation what measures can be taken for strengthening activities in the field of occupational health The board also approved publication of expert committee reports on plague, mental health, and nutrition, and it reviewed the procedure for the selection of non proprietary names for drugs

Faculty of Anæsthetists

On June 3 Lord Nuffield received the diploma of honorary fellowship of the Faculty of Anæsthetists of the Royal College of Surgeons of England At a luncheon in the college after the ceremony, Dr Bernard Johnson, dean of the faculty, proposing the health of the new fellow, praised Lord Nuffield's foresight and originality in proposing and endowing the chair of anæsthetics at Oxford University, and, he added, the new Nuffield College of Surgical Sciences, presently to appear next to the Royal College of Surgeons, would include provision for research in anæsthesia These generous gifts would benefit the practice of anæsthetics throughout the world Lord Nuffield spoke warmly of Prof R R Macintosh's work in the Oxford chair of anæsthetics He thought that the anæsthetist's job should certainly include the responsibility of deciding whether the patient was fit for a particular form of anæsthesia, in the past the surgeon had often had to accept this and other duties that could usefully have been undertaken by the anæsthetist

---

Number 4 of the *Proceedings of the Society for the Study of Fertility* which has now been issued covers the conference held last year in London The proceedings are published for the society by W Heffer & Sons Ltd Cambridge at 10s

The 10th edition of the *Register of Speech Therapists* is obtainable without charge by doctors from the Board of Registration of Medical Auxiliaries Tavistock House (North), Tavistock Square London W C 1

Letters to the Editor

THE NURSE'S RESPONSIBILITY

SIR,—Your leading article last week will give rise to criticism. It suggests that the doctor wishes to shift much of his responsibility on to the nurse's shoulders. The Royal College of Nursing is a highly organised body for which I have great respect, but it does not seem anxious to move with the times and recommend ways and means for the young nurse to gain an extra skill which, as you state, she enjoys. I use the word "nurse" in its legal sense of a State-registered nurse. I shall try to put the case of the house-officer, who has no organised body behind him, and I shall make some suggestions to remedy what may become a deadlock.

Many house-physicians are responsible to physicians for some forty "acute" beds. They probably assist in three outpatient sessions weekly and do a share of casualty. They are called at night for emergencies. They have a half-day off a week, every third weekend, and a fortnight's holiday for every 6 months of service. Theirs is a busy life with no thought of a 48-hour week or 96-hour fortnight.

The problem of the house-officer's and nurse's responsibility is exemplified by a patient admitted with suspected diabetes. At outpatients it is decided that a glucose-tolerance test is needed. All will agree that the early morning is the best time. Is the house-officer to be called five or six times for this, or should a nurse be trained to do this as a part of her nursing duties? I maintain that she can be taught and also that she is doing more useful work than any other nursing activity for him or her. I will forge the routine temperature, pulse, and respiration record if need be. If the diagnosis is confirmed, she will later teach the patient to test his urine for sugar and acetone, to understand his diet, and to give himself insulin. I can quote a case of a patient who died because he infected himself when he gave himself insulin, and I have no doubt whatever he would have done the same if a doctor had taught him. Single cases like this make bad laws. The disaster you record was not due to the nurse's getting "a reading of less than 80 mm. Hg," but to group-A blood being supplied instead of group-O.

What therefore is the remedy? Whoever performs these special tasks should be trained. That principle is already established for midwives. Nurses, after becoming S.R.N.S, should have a 6–12 months' course in a medical, surgical, or other ward and be taught the special procedures. Postgraduate education would also be given, best done by ward-rounds; and at the end she should be given a diploma comparable to the S.C.M.

In the early 'thirties THE LANCET organised a Commission on Nursing which did great good. The time is now ripe for another commission to decide who, in the best interests of patients and realising the limitations of medical and nursing personnel, should carry out certain procedures.

Rugby. R. E. SMITH.

THE ILLEGIBLE CANDIDATE

SIR,—May a layman express regret at the defence of illegible writing that has appeared in your columns? Doctors are often accused of bad writing, but I never thought to find them complacent about it. Sir John Conybeare's defence of it (May 16) rests on the assumption that a man's handwriting is finally stabilised in his twenties; but he offers no proof, and in fact the evidence is to the contrary. I know of many who have reformed or changed their hand, at all ages up to 60; I have never heard of anyone who tried to do so and failed. I changed my hand when I was 22, in preparation for an examination where bad writing was penalised. It took only a few hours stretched over three days, and left me with a handwriting which was easier not only to read, but also to write, since it was less jerky.

Bad writing is more like bad manners than bad features: it is unpleasant to the beholder, like an ugly face, but, unlike it, is easily corrigible. There is little excuse for anyone to emerge from a liberal education with so antisocial a habit, and therefore much to be said for penalising illegibility in examinations, provided always that students are forewarned and helped to improve their writing. This is not difficult, as there are plenty of good examples and manuals available, and anyone can teach himself. *Nullius in verba:* but could not Guy's try an experiment?

Stansted, Essex. E. W. Playfair

EFFECT OF GLUTAMIC ACID ON THE COMA OF HEPATIC FAILURE

SIR,—We have read with interest Dr. Walshe's preliminary communication (May 30). We have treated one similar case with a single dose of 20 g. of glutamic acid introduced through a stomach-tube, passed while the patient was in coma. Since we obtained a gratifying response we feel it worth recording this case briefly.

A man, aged 29, suffered from infective hepatitis in April, 1950. The attack did not appear to be severe and he was not immediately admitted to hospital, but shortly afterwards he developed ascites which necessitated paracentesis on two occasions. He was treated with a high-protein diet and recovered sufficiently to return to work after a few months.

He was admitted to hospital a year later with a recurrence of ascites but again responded to treatment. He remained at work for a further year until October, 1952, when he had a sudden hæmatemesis. This was followed by a period of alternating violence and semi-coma lasting 36 hours. Nevertheless he left hospital in a few weeks and continued at work until May 9, when he had a further hæmatemesis of about $1^1/_2$ pints.

He was readmitted to hospital in a rational state, but 16 hours after the hæmatemesis he became extremely violent for a period of 3 hours and then lapsed into deep coma. Treatment with glucose, B vitamins, and plasma was given for 4 days without apparent benefit. Liver-function tests were not significantly altered compared with results obtained on previous admissions; these showed only moderate impairment of liver function, as in Dr. Walshe's second case. However, chromatographic examination of the amino-acids present in the cerebrospinal fluid on the 4th day of coma showed a striking increase of glutamine. It was therefore decided to give 20 g. of glutamic acid suspended in 20 oz. of water introduced through a stomach-tube. All other treatment was stopped. Within 8 hours the patient became less comatose, and 24 hours after the glutamic acid had been given he was sitting up in bed eating breakfast.

During the last decade, and especially during the war years in Egypt, we have treated several cases of hepatic coma with intravenous glucose, B vitamins, and plasma. Although on occasions we have obtained some response to this form of treatment we have not hitherto observed such a striking recovery as that which followed the administration of glutamic acid. We agree with Dr. Walshe that this form of treatment deserves further trial.

W. M. PRIEST
T. P. WHITEHEAD
Warwick. S. R. F. WHITTAKER.

SIR,—We have read with great interest the preliminary communication by Dr. Walshe, as during the past three years we have been treating cases of delirium tremens by oral administration of glutamic acid. We hope to publish our results later; but in view of the interest aroused by his article it was thought that our findings should be disclosed now.

CHEMICALS AND FOOD

A RECONSIDERATION *

E C Dodds

MVO, MD, DSc Lond, FRCP, FRIC, FRS

COURTAULD PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON, AT MIDDLESEX HOSPITAL MEDICAL SCHOOL

It is generally admitted that certain subjects, when introduced into a conversation, have the curious power of robbing the talker of his powers of logic They appeal so strongly to the emotions that they are seldom considered coolly and critically

High on the list of these dismissers of reason and logic is the question of food One only has to think of the brown versus white bread controversy to realise that this is so Even the dignified calm of the Upper House has been rent by sharp cries of the noble contestants in this famous controversy Similarly, adulteration and chemical treatment of food has an irresistible fascination for the press Journalists seem to take a delight in painting pictures of people sitting round a family table eating what looks like a fine and wholesome meal yet is really a poison

Last year in this very room Sir Edward Mellanby thrilled and horrified an audience with his cinematograph pictures of dogs suffering from running fits due to eating treated flour Observations such as his must of necessity focus the attention of the public, and also of the medical profession and scientists in general, on this question of the chemical treatment of food But we should, I believe, be wrong to judge such treatment by the few alarming exceptions which it is possible to quote It is not true, as the general public is sometimes led to suppose, that food manufacturers can do what they like with the people's food, but, even if there were no supervisory authority to control them, it seems unlikely that these manufacturers, who, after all, must be astute business men, would deem it sound policy to produce products that would eventually poison their customers I think it must be admitted that there is a first check in this respect by the manufacturers themselves—though unfortunately it must also be admitted that this has not stopped them making mistakes in the past from lack of knowledge

Preservation of Food

Chemicals may find their way into food either accidentally or deliberately, but in this lecture I am considering only those which are added deliberately for some specific purpose Again, I shall have nothing to say about the addition of substances for the purpose of misrepresenting the food—though on occasion such fraudulent practices have of course had serious results

From the earliest times man has been interested in doing things to his food, either by treatment such as cooking or by the addition of substances for various purposes The main purposes of the additions are (1) to alter or improve the taste of the food, and (2) to preserve it We are not not concerned here with substances like spices, which were originally employed to cover the fact that the food was often slightly putrid Far more important is the preservation of food, which in the past has been the main object of adding chemicals

That food needs preserving is obvious when one thinks of the seasonal nature of its production, also it has to be stored for periods of want and famine, and for purposes of travel The classical methods of preserving it were drying, salting, smoking, and refrigerating To these were later added the methods which we now know as hermetically sealing—the art of sterilisation—which was used for vegetables in glass jars as far back as the 17th century but became of great importance when the canning industry was firmly established towards the end of the last century All early attempts at food preservation were handicapped, however, by lack of knowledge of the cause of putrefaction It was firmly believed that putrefaction was due to a spontaneous process occurring in the tissues of the food when kept in presence of air, and it was felt that if all air could be excluded putrefaction would be arrested Later the cause of putrefaction was put down to the oxygen in the air, and storage in an atmosphere of nitrogen was recommended to prevent it Not until the middle of last century was the true nature of the putrefactive process understood, through Pasteur's demonstration that it was airborne microbes, not the air itself, that caused putrefaction

Just as Lister in surgery used carbolic acid sprays to eliminate microbial action as a cause of infection, so did the food manufacturers try to use powerful antiseptics in the preparation of their products Thus in the 1870s we find such powerful substances as formalin being extensively employed, particularly as a preservative for milk The surgeon quickly learned that it was better to exclude the micro organisms, by the process of asepsis, than to kill them by the violent and harsh process of antisepsis The food manufacturer learned this very much later, and we see the persistence of powerful antiseptics in food long after antiseptic surgery had disappeared

Many people unthinkingly ask why it is necessary to add chemicals to food at all The answer is obvious —namely, that if one has a highly urbanised population such as we have in this country one must be able to preserve their food Unless a person lives on a farm by the sea, his milk, butter, eggs, and fish must be brought from a considerable distance, and this in itself demands some form of preservation So long as our population is of the size it is, and is grouped in large cities and towns, some form of chemical treatment of food is an absolute necessity Again, the preservation of food enables the products of other lands to be enjoyed

If we accept the thesis that food preservation is essential, we can turn to the two vital questions of the methods to be used and the way in which these methods should be controlled by the Government Let us consider first the question of control

Control and Supervision

From the time of the Norman Conquest our legal records show a continuous series of prosecutions for contaminating food or for purveying food unsuitable for human consumption In the absence of detailed laws and regulations, however, prosecution depended largely on the opinion of the prosecutors The control of many of the food industries was in the hands of guilds—the vintners, the bakers, the salters, and so forth—and supervision was vested in these City companies The methods they employed make interesting and amusing, if unscientific, reading It must be remembered that chemical analysis was rarely applied to food before the last century The only form of analysis of a Governmental nature that was performed was undertaken for the Board of Excise at Somerset House, which needed an estimate of the alcohol content of beverages imported into the country

As chemical theory and practice developed, it was natural that the Government should turn to the newly developed science of analytical chemistry, and in 1842 the first Government laboratory was set up in Somerset House for the Board of Excise In 1875 the laboratory facilities were considerably extended, and Dr James Bell, who was appointed in 1875 as head of the labora-

---

* Sanderson Wells Lecture delivered at the Middlesex Hospital on May 20, 1953

In all, some twenty cases of delirium tremens have been treated by this method, giving 12–16 g. of glutamic acid daily by mouth or, in restless patients, by tube feeding. The first few cases were also given vitamin B_1 100 mg. intramuscularly daily, but later cases were given glutamic acid alone, and showed equally favourable results. Within a few hours the restless delirious patient becomes quiet and easily managed, and within a week he has usually become rational, so that treatment can be discontinued.

The possibility has occurred to us that the mental symptoms of delirium tremens might be due to a disturbance of brain metabolism secondary to hepatic failure. Two of the patients had been jaundiced, and recent investigations by chromatography have shown biochemical similarities with cases of hepatic failure. Mental confusion, restlessness, and delirium are moreover common in hepatic failure; but so far as is known no instance has been reported where visual hallucinations were present, though these are a fairly constant feature of delirium tremens.

RESEARCH ON POLIOMYELITIS

SIR,—In your annotation of May 30 you ascribe to me the observation that there is a high prevalence of paralytic attacks of poliomyelitis in school-teachers. This is not in accordance with my experience. I did, however, draw attention to the fact that a disproportionate number of patients in the recent outbreak of poliomyelitis in Southend-on-Sea came from the families of, or were intimately associated with, school-teachers.

Municipal Health Centre,

Medical Officer of Health.

THE PROBLEM OF PEPTIC ULCERATION

SIR,—The repeated writings on peptic ulceration by a surgeon of such eminence and standing as Sir Heneage Ogilvie must inevitably induce many of our younger colleagues to regard the operation of partial gastrectomy as one which not only gives absolute cure, but is also unaccompanied by any long-term postoperative ill effects. The student of medicine with lesser experience may even wonder why the physician attempts to cure the condition by a long period of inpatient hospital treatment when but a fortnight's stay, accompanied by a gastrectomy, will cure the condition once and for all. He may wonder too, why it is suggested that those of a younger age-group, in which duodenal ulceration predominates, should be advised to restrict their normal way of life, when the operation would seem to be as beneficial to them as to older sufferers from this condition.

As a result of long apprenticeship to surgery, in which I have had the privilege of being house-surgeon and registrar to a number of distinguished surgeons, and because of my own personal experience, I am convinced that postoperative ill effects occur in a very substantial number of patients, especially when the operation has been performed for duodenal ulcer. They have certainly occurred amongst the patients of all surgeons for whom I have worked and also in my own series. Judging from the reports in the literature these disabilities are a widespread experience of many surgeons. Cattell told me in a private communication that only 85% of his patients are symptom-free following a gastrectomy, and that in 5% ulceration recurs.

If gastrectomy is the perfect operation for peptic ulceration of all types, research into other ways and means of curing the condition is a waste of time. I believe, however, that this mutilating operation, which removes an essential part of the digestive tract, does not give anything like perfect results, and that further research for the cure of a condition which seems ever increasing in its numbers is essential.

I have previously described an operation applicable to cases of duodenal ulceration in which the stomach is preserved.[1] My experience of this operation, in approximately 100 cases, suggests that, so far, it is greatly preferable to a gastrectomy in such a condition, and the results will be reported shortly.

Although the patients of one surgeon may very seldom have disturbances following gastrectomy, there is no doubt that, whatever technique is used, these are, throughout the country, comparatively common, and we would be unwise to underrate their number.

London, W.1.

STANLEY AYLETT.

TUBERCULOSIS IN GLASGOW

SIR,—In the absence abroad of my friend, Dr. Brailsford, may I be permitted to reply to Dr. James's astonishing letter in your issue of May 30. It is true that Dr. James's address seems to suggest that he is "trailing his coat," but nevertheless there is a possibility that some of his arguments will be taken at their surface value.

Dr. James complacently states that there is no evidence that good housing and a good standard of living will eradicate tuberculosis; in fact there has been such evidence for two or three generations right throughout the world. It is well known that in this country tuberculosis is and always has been very much less common amongst the well-to-do than amongst the poor, and the general difference between these two groups has been, not their access to doctors, but the good housing and the good standard of living which the well-to-do have enjoyed. The two world wars brought to Europe a sudden deterioration in living conditions, and in each case the falling incidence and death-rate from tuberculosis both were interrupted in a disquieting fashion to fall again when more normal conditions of nourishment and living returned. In Scandinavia, which probably enjoys the highest standard of living in Europe, the death-rate and incidence of tuberculosis have steadily declined long before the discovery of modern antibiotics, and although much of this may be ascribed to vaccination it may safely be claimed that most of it is due to a high standard of living and housing. Is Dr. James aware of the epidemiological history of, for example, the Netherlands and Germany during the late war? The Dutch passed through greater malnutrition than almost any other nation in Europe, and by 1945 the incidence of tuberculosis had risen to 208% of the normal. In Germany, Poland, Hungary, and Austria a similar position arose.

It is surely ironical to suggest that the solution of the tuberculosis problem depends on a "final assault" on an "extremely resilient organism," especially during a period when every civilised nation is vigorously engaged in injecting live tubercle bacilli into the largest possible number of their *non-tuberculous* subjects! More than 40 million persons have been vaccinated during the past few years, and each year there are in the world more persons infected with tuberculosis and fewer with tuberculous disease.

The tubercle bacillus is ubiquitous, and it is ridiculous to suggest that the disease can be conquered by physical eradication of the organism itself. History does not give any instances of the eradication of any such epidemic disease in this way. Diphtheria has been conquered in this country, not by treatment of the disease itself, not by any mass attack on the *corynebacterium*, but by immunisation of the host; and for the past half-century tuberculosis has been attacked in the same way. It will not have escaped general notice that tuberculosis is less common in the civilised countries with a high standard of living and most deadly in countries where the standard of living and housing is low. Dr. James would do well to read the transactions of last year's Commonwealth Health and Tuberculosis Conference in London, in which tory, became responsible for analysing not only alcoholic beverages but also food and drugs In the same year the first important Act controlling chemicals in food and the composition of drugs was passed and in 1893 an Act dealing with fertilisers and feeding-stuffs brought a further inrush of work The Government Laboratory, as we now know it, was brought into being by the appointment of Sir Edward Thorpe in 1894 as the first Government Chemist This post has been continued to the present day, and its scope and importance have increased from year to year To get an idea of the amount of work now required, compared with what was required in 1894, one has only to think of the advances since that time in biochemistry, chemistry, and nutritional science in general In 1894 we had no knowledge of even the existence of the vitamins apart from certain hints with regard to the antiscorbutic factor of lemon juice and the possible bearing of rice polishings on beriberi

THE LANCET'S CAMPAIGN

The attention of Parliament and the public was focused on food adulteration towards the middle of the last century by a very curious series of writings and happenings conducted by THE LANCET The first editor Thomas Wakley, is well known to all readers of the period as one of the outstanding figures in medical and other reforms of the day This fiery courageous man jumped into the most dangerous of situations without any thought for himself or for the financial implications in which he might involve his journal During the years approaching the middle of the century he became more and more worried about the adulteration of food and decided to found in 1850 a body which he called THE LANCET Analytical Sanitary Commission This flourished from 1851 to 1854 inclusive—i e , for about four years The principal analyst attached to the commission was Dr Arthur Hill Hassall, who was born in 1817 and died in 1894 He had been trained as a doctor under the old system of apprenticeship in Dublin, and came to this country to set up in general practice He was admitted to membership of the Royal College of Physicians, but during his early training he came under the influence of Sir William Hooker, director of Kew Gardens, and became not only an excellent botanist but a trained microscopist As an expert on the application of the microscope to botanical specimens, such as seeds, he had peculiar knowledge of the job that Wakley had in mind With Hassall at the head of the team, Wakley examined some 2500 samples of food during the five to six years from 1850 onwards A high proportion of these were found to be adulterated, and in order to bring the matter to the attention of the authorities Wakley published the names of firms, suppliers tradesmen—in fact the name of everyone connected with the exploitation of the particular food These were all published openly in THE LANCET One can well understand the anxiety of Wakley's friends and relations during this period, for some of the companies and individuals mentioned might well have brought legal proceedings against him, and a successful action of this kind would probably have ruined him and his enterprise

As a contemporary put it a gun suddenly fired into a rookery could not cause a greater commotion than did the names of dishonest tradesmen ' Nearly 3000 names were published yet only one legal action was started, and this was dropped The type of adulteration varied from relatively harmless frauds such as the dilution of coffee with chicory to some very dangerous adulterations employing sugar of lead, mercury, sulphuric acid, and even nitric acid in vinegar It is estimated that as a result of these publications adulteration of food dropped from 65% to under 25%

In 1855 Hassall published a book called *Food and its Adulteration*, and this included the report of THE LANCET Analytical Sanitary Commission This was the spearhead of the attack, and the same year saw the appointment of a Parliamentary committee, under the chairmanship of Mr Scholefield to investigate the whole question of the chemical treatment and adulteration of food In its report published in 1856 this committee pointed out that not only were the public defrauded but their health was endangered, while the export of adulterated food would damage our prestige overseas

LEGISLATION

As a result of these activities the first Adulteration of Food and Drugs Act was passed in 1860 Though it only scratched the surface of this very difficult problem, credit must be given to those who devised it for foreseeing the need for the appointment of public analysts to the various cities and corporations Unfortunately the Act did not make it compulsory to appoint them and there was therefore no adequate machinery for enforcing the law The first public analyst was Dr Letheby, for the City of London, but it is reported that in the first three months of his office he examined only four samples of food—all of which were adulterated

When this 1860 Act was found to be largely in abeyance, a new one was passed in 1872 This imposed severe restrictions on manufacturers and purveyors of food, and it caused a strong reaction in the food manufacturers, who, it is said, influenced Parliament to produce a third Act in 1875 which was more favourable to them This 1875 Act, despite its shortcomings remained in force for sixty years and was not revised until the 1930s Its two principal points were first that nothing injurious should be added to food and secondly that the food when supplied to the public must be of the nature, substance, and quality demanded by the purchaser When one considers how difficult it is today to decide whether a chemical is poisonous or not, one can well understand the difficulties that faced those trying to administer the Act of 1875 Again it is a tribute to the 1875 Act to note that there has been a steady fall in prosecutions and convictions for food adulteration since it was enforced

The success of the 1875 Act was due almost entirely to the early public analysts They developed methods of analysis which were able to withstand criticism in the courts, and these methods have been copied throughout the world Their position was further established by the arsenic in beer tragedy in Manchester at the turn of the century, when some 6000 people were poisoned and 70 died, and by the mayoral banquet at Winchester in 1902 when contaminated oysters caused many illnesses and 4 deaths The analytical work for many of these outbreaks if one can call them that, was undertaken by central authorities such as the Government Laboratory but it was soon found that these were too numerous to be attacked centrally and that more local organisation was needed 1906 saw the food departments of the Local Government Board constituted—mainly to deal with tinned meat from Chicago, which was found to vary widely in quality The Public Health (Regulations as to Food) Act of 1907 gave importing authorities the right to examine foreign meat and unsound food

During this period no special attention had been paid to milk, and it is interesting to note that after the Wakley affair there was an increase in the addition of powerful antiseptics such as formalin and borax, to many foods and particularly to dairy products By 1912 the authorities were beginning to be worried about milk and a Milk and Dairies (Consolidation) Act was passed in 1915, though it could not be brought into action until 1918 Amended in 1922, this Act defined the different grades of raw milk and prohibited the addition of any chemical whatsoever Pasteurisation was the only form of treatment permitted, and the authorities wisely con he would find some figures relating to the Commonwealth which would surprise him. Special attention might be paid to the incidence and death-rates in India and Pakistan. Dr. James, however, is most provocative when he suggests that at long last and for the first time tuberculosis is being tackled by modern drugs such as streptomycin, but the facts do not support him. The death-rate from tuberculosis in 1950 was approximately one-tenth of the figure 100 years previously, and during this century the drug treatment of the disease contributed practically nothing to its eradication. The fall during this 100 years was fairly steady and followed closely the steady improvement in the standard of living.

Dr. James again suggests that because the price of food has steadily increased during the past four years this is an argument to show that the standard of living has not affected the tuberculosis incidence or death-rate during this period. May I suggest that improved housing and improved standards of living do not miraculously and in a period of a weekend or even a full year result in the complete transformation of a badly nourished man. Improved housing and improved nutrition take years to operate, and it is an unchallengeable fact that the people in this country are enjoying a vastly higher standard of living than they did at any previous time of their existence. Even during the past four years the *real* standard of living has slightly improved.

The claim that the modern drugs will cure tuberculosis is a little premature, is it not? We are perfectly aware that patients treated by streptomycin and so forth have their deaths postponed, but there is no convincing evidence that they have been completely cured and no evidence whatsoever that all the mycobacteria in their bodies are completely killed.

While full acknowledgment must be made to the use of modern antibiotics as one of a half-dozen potent weapons in the fight against this disease, it still remains that their use is only one weapon, and it is fortunate indeed that this weapon was not discovered 50 years ago before the well-tried methods of prevention by attention to the well-being of the host had been shown to be so successful.

Public Health Department,
Smethwick, Staffs.

HUGH PAUL.

POSSIBLE HAZARD WITH SUXAMETHONIUM AND SUXETHONIUM

SIR,—Because of the increasing use of the short-acting muscle relaxants suxamethonium and suxethonium, we believe it desirable to draw the attention of anæsthetists to a possible complication when a procaine infusion is administered to a patient receiving either of these compounds.

Dr. Victor Goldman[1] reported some fourteen months ago that he had observed prolonged apnœa in a patient receiving procaine who had been given 60 mg. of suxamethonium cation followed six minutes later by a further dose of 30 mg. The first dose produced relaxation lasting four to five minutes, while the second caused most profound paralysis of thirty minutes' duration which necessitated artificial respiration with oxygen.

Since it is now known that pseudocholinesterase is responsible for the hydrolysis of both procaine and suxamethonium compounds, it is not inconceivable that the frequent use of procaine during thoracic and cardiac surgery in conjunction with the short-acting relaxants may give rise to further similar cases. Foldes et al.[2] have recently confirmed the observation of Goldman both experimentally and clinically. The intravenous injection of procaine during suxamethonium administration increased the inhibitory effect of the latter on neuromuscular transmission, resulting in increased respiratory depression in patients and a decreased response of the sciatic-gastrocnemius preparation to electrical stimuli in animals. Foldes et al. also demonstrated in vitro substrate competition for pseudocholinesterase between procaine and suxamethonium.

It seems important that anæsthetists should be aware of the possible additive effects of these agents.

C. R. DAY.

MISDIAGNOSIS

SIR,—In your excellent annotation of May 23 you quote Professor Bürger, who poses five direct questions to the clinician who has been mistaken: (1) was a thorough physical examination of the patient undertaken? (2) were diagnostic investigations carried out—and which? (3) was the history properly assessed? (4) were the signs correctly evaluated? (5) were there superadded symptoms obscuring the diagnosis?

This reminded me at once of the last paragraph of Sir William Osler's book *Diagnosis of Abdominal Tumors*, published in 1902:

> "Amid many pleasant memories of Berlin. just twenty years ago this session, none recur more persistently than those associated with that true Asclepiad, Ludwig Traube, who, adding probity to learning, sagacity, and humanity, reached the full stature of the Hippocratean physician. When acknowledging some error he would say—often in a soft, meditative manner, as if gently reproaching himself—Have we carefully observed all the facts of the case? Yes. Did the art permit of a judgment on the facts under consideration? Yes. Did we reason correctly upon the data before us? No. Wir haben nicht richtig gedacht. And with these significant words—may they long echo in your ears!—let us close the exercises of the session."

Tonbridge, Kent.

P. T. COOPER.

JUNIOR MEDICAL STAFFING

SIR,—I think that the article by Mr. Hurst and his colleagues in your issue of May 23 calls for further comment.

The authors appear to base their claim that there are too few doctors on the fact that there are fewer entrants to the medical schools each year than there are preregistration posts; but they seem to forget the fallacious appearance of shortage of doctors at junior hospital staff level owing to many of these doctors being temporarily in the Forces. In any case they should surely base their estimate on the number of permanent established medical posts available (hospital, general practice, local authority, Forces, industry, Colonial Service, &c.) unless they envisage a new grade of permanent junior house-officer. If they will study the figures of the total number on the Medical Register and the numbers of posts available in the various major sources of permanent employment as above listed, they will scarcely fail to be struck by the fact that these established posts account for little more than, if as many as, half of the 83,914 doctors already registered. (It is worth recalling that the numbers on the Register in 1933, 1940, and 1946 respectively were 56,741, 64,679, and 76,292: and there have not been so many retire or emigrate.) Sober calculation shows that there is already an overabundance of doctors, though admittedly there are anomalies in distribution. Are the authors not aware of the plight of the senior registrars and of many others in, or not even in, unestablished medical posts? It is high time that medical man-power figures are looked at as a comprehensive whole right from student to professorial, general practitioner, and consultant level.

Some of their suggestions for remedying this alleged shortage of doctors are open to question. The employment of non-medical technical assistants to carry out

1. Personal communication.
2. Foldes, F. F., McNall, P. G., Davis, D. L., Ellis, C. H., Wnuck, A. L. *Science*, 1953, 117, 383.

centrated on the production of better conditions in the preparation and distribution of milk

FOOD STANDARDS

A study of food standards was begun in 1886 and a Select Committee of the House of Commons suggested the formation of a Court of Reference to deal with standards But no real progress was made until after the 1914–18 war

Between 1919 and 1934 a large number of committees were appointed to consider the control of the quality of food and of various substances added to it—e g , colouring matters and flour improvers Out of the report of an interdepartmental committee in 1934 came the new Food and Drugs Act of 1938 This Act was never fully used owing to the imminence of the war, and when the Ministry of Food was formed the Ministry became the operative authority

At the present time yet another Act is being worked upon, and in the near future we may expect an Act which will embody the experience and wisdom gained from 1850 onwards The Ministry of Food has returned to the old problem of devising standards for food, and today there exists a Food Standards Committee which is in process of laying down the requirements

Chemicals in Food

As things stand at present, with few exceptions the manufacturer can add to food, or treat food by chemical process, without obtaining the permission of any Government department But though no Government department is officially charged with advising manufacturers of the toxicity of chemicals added to food, the Ministry of Food is frequently consulted and has given very valuable advice on the use of chemicals in food

MINERAL OILS

The addition of mineral oils to food became a common practice in the early part of the war Fat was scarce and the addition of pure liquid paraffin to certain food products increased their keeping qualities and palatability Researches officially instituted showed, however, that the addition of liquid paraffin was actually dangerous in that it reduced the absorption of certain vitamins, while the paraffin itself might be absorbed and deposited in certain parts of the body In 1949 its use was prohibited

ETHYLENE GLYCOL AND DIETHYLENE GLYCOL

The use of these substances as solvents for sulphanilamide led to the death of 107 persons in the United States, and it is amazing that this could happen in a country so far advanced in the control of substances offered for sale Another American tragedy was caused by the use of ortho-cresyl-phosphate as a substitute for ginger It produced serious permanent damage in the central nervous system

FLOUR IMPROVERS

After Sir Edward Mellanby's classical experiments on the production of running fits in dogs by feeding them with flour treated by nitrogen trichloride, it was only natural that alarm was caused in both official and lay circles The first question that the layman asks is "why have flour improvers at all ?" and he reinforces this by the statement that improvers are not used in certain countries such as France The answer is very simple In this country during the last fifty years the small baker has gradually been replaced by the big scale bakers known as "plant bakeries" This has resulted in shortening the time of production of the loaf and has simplified delivery On the other hand, the operation of a plant bakery demands a rigidity of process which is unnecessary for the small baker

It must be remembered that the composition of flour varies very considerably from time to time The British miller has to depend on imported wheat and wheat from different districts, and his flour will vary in its behaviour in the bakehouse The small baker can modify his baking process, time of fermentation, and so on to allow for these differences in the types of flour, but the plant baker cannot do this In order to overcome this difficulty the chemical treatment of flour, with so called improvers, was devised. Acting on the gluten of the flour these chemical agents change its physical properties and make its behaviour, as regards baking, more or less constant Most improvers are oxidising agents, and substances such as bromates and persulphates have been employed About thirty years ago the treatment of flour with gaseous nitrogen trichloride was introduced it had the same effect as prolonged storage and was called the "agene" process Nutritional experts have always been a little unhappy about the use of highly reactive chemicals, and in 1923 Mr Neville Chamberlain, then Minister of Health appointed a departmental committee to study the treatment of flour with chemical substances The report of this body, issued in 1927, makes fascinating reading, for the committee seems almost to have foreseen the work of Sir Edward Mellanby Paragraph 54 reads

> "Our observations upon chlorine apply also to nitrogen trichloride It is true that the quantity of the latter substance used per sack of flour is very much less than the quantity of chlorine introduced in the chlorine process, but nitrogen trichloride is very highly reactive, and evidence has been given that its action on the protein of flour is probably similar to what we have already described in the case of chlorine We are, therefore, compelled to extend our disapproval of chlorine to nitrogen trichloride also"

This paragraph has a distinctly prophetic tone, although at that time there was no evidence that improved flour had any biological properties other than those of normal flour The subject is now receiving the most careful attention by all concerned

COLOURING OF FOOD

The use of dyes is a very old practice in fact the oldest records of food include descriptions of how to make it more attractive in this way The early pigments were natural ones and therefore free from risk burnt sugar was used to give food a rich brown colour, while cochineal and similar pigments were used for sweets With the development of the synthetic dye industry the use of dyes in food was greatly increased At first no thought of harm occurred to the official mind, which was concerned mainly with the possibility of colouring to make foods appear better than they really were

Towards the end of the last century the attention of health administrators was drawn to the so-called aniline workers' cancer This was a malignant papillomatosis, occurring in the bladder of a significant proportion of persons engaged in the production of aniline dyes A great deal of hard work has been done on this problem and we now know most of the compounds responsible, which incidentally do not include aniline itself Some of the compounds used in the colouring of food were known to belong to this series of cancer-producing substances, and the question of control immediately arose One method is to follow the American practice and issue a *permitted* list of compounds This consists of some 20 pigments which have been subjected to extensive pharmacological and biological study, and the American industry is said to be able to manage with these The alternative is to compile a *prohibited* list, and it is this technique which has been adopted by our own authorities It is giving away no secrets to say that the official mind is much concerned about the present position, for the English method virtually gives carte-blanche to the manufacturer to colour his wares with any pigment provided it is not on the proscribed list preliminary investigations on patients is wasteful and psychologically harmful; in short it is push-button medicine at its worst, as any experienced clinician knows. Are lay administrators really the right people to advise on these matters? And do members of our profession really think that more and more regulations should be made forcing longer hospital service on all young graduates, forcing whole-time status on consultants, and barring doctors from more non-clinical, presumably medical administrative, posts?

C. D. NEEDHAM
Aberdeen. Consultant Physician.

SIR,—Dr. Greenwood Wilson suggests, in his letter last week, that the junior resident staff in the National Health Service are nowadays too concerned with working hours and conditions. He then gives us an account of his days as a houseman at Westminster Hospital when apparently he never knew that time existed. Presumably this description is meant for comparison with present-day disgruntled house-officers. Such an attitude of mind is all too common among senior medical men, but it disregards several important factors.

Firstly, since the days when Dr. Wilson was a houseman the practice of medicine has undergone considerable changes. The modern resident doctor is responsible for the proper management of complicated techniques unheard of thirty years ago. Instead of remaining impotent by the bedside counting the pulse and percussing the chest, he is able to carry out active measures which require thorough knowledge of many branches of medicine.

An obvious example is intravenous-drip therapy. This requires among other things a knowledge of the technique of blood-grouping and cross-matching, together with a basic understanding of the electrolyte balance of the body under both normal and abnormal conditions. At the same time the conscientious houseman will keep a close watch to see that the patient is being neither over- nor under- "dripped." Finally the actual setting up of the drip requires a certain degree of manual skill, particularly in severely dehydrated infants.

Another example is tuberculous meningitis. In the days of Dr. Wilson a patient with this disease slowly slid into the necropsy room, whereas now the management of such a case requires months of special daily treatment, the bulk of which falls on the houseman.

Surely these procedures carry more responsibility than those practised in the time of Dr. Wilson.

Secondly, since the end of the war the majority of housemen have encountered some form of National Service. Either they are ex-Servicemen who have taken up medicine since leaving the Forces, or they have to contend with two years of National Service after finishing their house-appointments. As a result nowadays the average doctor has to wait longer for a settled existence than his more senior colleagues. Does Dr. Wilson really imagine that an ex-Serviceman with, for example, two children is happy to find himself on the threshold of his chosen career, being rewarded with £1 a week and all found, including laundry, plus the odd theatre ticket from the matron's office?

If Dr. Wilson chose to become resident in any National Health Service hospital for only a week, I am sure he would discover that the great majority of housemen are just as conscientious as in his day. This does not prevent them from being sufficiently intelligent to ask for better working conditions.

Waltham St. Lawrence,
Berkshire. M. ANTHONY PEYMAN.

SIR,—I cannot, as a houseman, let Dr. Greenwood Wilson's letter go unchallenged.

I take it that it is some considerable time since he was a houseman. During the intervening years the value of the pound has altered somewhat, not to mention the rate of income-tax. From what one gleans from the consultants today, the pound-a-week houseman did occasionally lean on his parents, and in the years before the late war parents could afford to subsidise their housemen sons. Nowadays, as Dr. Wilson probably has noticed, there is less money about, and most parents expect their children to keep themselves on completion of their medical-school education.

One hears so many hard-luck stories today, on the lines of "the senior registrar with a triple fellowship who had to take up chicken-farming," that not many newly qualified men will gamble on the poor odds of reaching consultant status. Hence, they do a minimum time in hospital and endeavour to get into general practice and, they hope, Security.

At one time one had only to remain on the house staff for long enough to be fairly certain of a staff appointment. This is no longer so—hence the shortage.

May I assure Dr. Wilson that some of us at least are managing to be "happy round the clock," even if we don't get any theatre tickets from matron's office?

General Hospital,
Nottingham. R. W. POOLE.

KWASHIORKOR

SIR,—I am beginning to feel that we are making rather heavy weather over this word, and perhaps the time has come to simplify the whole issue. When I attended a conference in The Gambia last November one of the members described finding a child with this disorder in an up-country village in West Africa. He asked an old granny what it was called, and she knew the name. He then asked her what the name meant, and she said "the deprived child." This seems to me to be a far better explanation than to drag in red devils and other mythology. In any case it so exactly describes the child concerned that the story has the ring of truth.

Institute of Child Health,
The Hospital for Sick Children,
Great Ormond Street,
London, W.C.1. ALAN MONCRIEFF.

CONTRACEPTIVE TECHNIQUE

SIR,—The prejudice demonstrated by Dr. Marie Stopes (May 30) towards a much-needed progressive step in contraceptive technique must surely surprise many of your readers when she makes it clear that her disapproval is not founded on any clinical familiarity with the method she too readily condemns. In the curiosity she displays in its evaluation, however, there may be a brighter gleam of hope for the patient.

Copies of published reports following studies in evaluation of the effectiveness, tolerability, and acceptability of the 'Preceptin vaginal gel' method are available to Dr. Stopes—or to any interested medical practitioner—on request to the professional service department of this company. Supplies of the gel are also available to any clinic at moderate cost.

REGINALD GEORGE
High Wycombe, Managing Director,
Bucks. Ortho Pharmaceutical Ltd.

OPHTHALMIA NEONATORUM

SIR,—There would, I think, be fairly general agreement with Dr. Williamson's contention, in his letter last week, that the number of cases of ophthalmia neonatorum notified must represent but a small proportion of minor conjunctival infections in the newborn; but it is surely because they are limited to the conjunctiva that they respond to purely symptomatic treatment. Such treatment may include penicillin or, as Dr. Williamson suggests, other antibacterial agents.

Your recommendation of penicillin, however, was for the *prophylaxis* of gonococcal ophthalmia which, with its almost inevitable corneal involvement and very serious prognosis in spite of treatment, must be regarded in a very different light from the "sticky eye" which is now the only form of neonatal ophthalmia commonly seen in this country. The consequences of abandoning

Again the layman asks "why colour food?" Excluding fraud, with which we are not concerned here, there can still be no doubt that the use of pigments in certain food preparation is essential Sweets, jams, and confectionery would look very drab if they were not coloured, and the public would certainly take a considerable time to get used to uncoloured products But the protection given to the public must obviously be as complete as possible

Better Protection of the Public?

Presuming, as I think we must, that under modern conditions the chemical treatment of food, or chemical additions to food, are necessary, we can examine the question of whether the existing *regulations* are satisfactory and what can be done to improve them As I have already said, the whole subject of the Food and Drugs Act and of the regulations regarding preservatives is at present being reconsidered, and therefore one can speak only in the broadest possible terms Clearly, however, a new Act would embody the experience gained by the Ministry of Food during the war, and one can predict that many of the war-time orders of the Ministry will be included in the new Act or regulations made under it What is perhaps more appropriate for us to consider is whether sufficient information about the power of chemical substances to injure health is available, and (if not) how and by whom can it be acquired?

A great deal is known about the toxicity of a number of substances used in the food industry The minimum lethal dose, for rats and mice, of most of these substances is well known, but this of course does not give the food technician the answer that he wants He wants to know what would be the effect of consuming a minute quantity daily of a given substance during the course of a life time It is obvious that no-one possesses this information

Prof A C Frazer has given a great deal of study to this question and has suggested a series of tests Very briefly, he suggests testing the compounds at various levels for acute toxicity and lays down a very rigid lethal dose above which the compound should in no circumstances be employed by the food manufacturer To try to assess the compound over a longer period he has devised a test in which three generations of laboratory animals are exposed to the drug or chemical When the rates of growth, reproduction, and so on, of these animals remain unchanged, it is concluded that the substance is possibly harmless This appears to be a very reasonable assumption, and it is difficult to see how better information could be obtained within a reasonable time

The next and vital question is "who is going to do this work?" The amount to be done is enormous Should it be done by a central laboratory? This would be rather cumbersome, and the charge, surely, should not fall on public funds Perhaps a series of laboratories which produce chemicals for food could undertake the work, and many of us would think the *onus of proving* that a substance is harmless should properly rest on the shoulders of those who propose to use it Some chemical manufacturers have established very elaborate laboratories where extensive experiments of the type described are conducted and they are able to recommend their products with every confidence that they have eliminated the risk of chronic toxicity '

An entirely new aspect of the problem has arisen through the use of insecticidal sprays on crops, for, unless great care is taken the food may be contaminated with traces of the insecticide used This important subject is being considered by a committee under the chairmanship of Prof S Zuckerman Again, the use of insecticides is an absolute necessity today because very large quantities of potential food are destroyed by insect pests

Conclusion

Discussions in many places show that there is a group of people—often highly scientific people with well balanced outlooks—who feel that the addition of chemicals *to food is fundamentally unsound* and that our aim should be to abolish any form of chemical treatment or addition to food The argument is an unsophisticated one, based on the grounds that "Nature has provided the food, and who are we to interfere?" But why should we apply this type of argument to only one aspect of our existence? If we are to adopt a "hands off Nature" attitude towards food, then logically we should adopt it towards all other aspects of living We certainly should not live in towns, and possibly we should not wear clothes It seems to me that if we accept the so-called advances offered by the technologists in heating, transport, housing, and so forth, it is reasonable to accept similar advances in the *technology of food*—always with the proviso that the procedures are controlled as fully as possible The solution to the problem of deaths on the road is not to ban all motor traffic but to control it in such a way that the deaths are reduced and eventually, one hopes, abolished Surely the same applies to food

Using preservatives and other means it is now possible to distribute food at a cost within the grasp of all, and to maintain a uniformity which would be quite impossible without the labours of the food technologist Surely we are not going to throw away all these advantages because *of one or two* unfortunate episodes in which a doubtful or bad process has slipped through the existing system of control? The moral is to *perfect* the system of investigation and control so that we can gain the full advantage of the work of the food technologist but at the same time make sure that we are not doing ourselves any harm

MANAGEMENT OF ANÆSTHESIA OF THE SEVERELY BURNED PATIENT

JOHN R ROOK
M B Edin, D A

CONSULTANT ANÆSTHETIST, BIRMINGHAM ACCIDENT HOSPITAL

DURING the five years from February, 1948, to February, 1953, at the Birmingham Accident Hospital increasing numbers of extensive burns have been treated each year, and, since *skin-grafting* is a life saving measure in these cases, the anæsthetists have accepted worse anæsthetic risks than previously

PREOPERATIVE MANAGEMENT

Severely burned patients are a group on their own and behave differently from any other type of injured patient The *motor-accident* case is admitted to hospital in a condition of surgical shock due to multiple injuries but, once resuscitation has taken place, the injuries can be surgically treated, whereupon the patient's general *condition improves rapidly* Not so the extensively burned patient because after resuscitation he has to wait for two or three weeks till the dead skin and other tissues have separated and the burn is ready for skin grafting During those two or three weeks of waiting the patient's general condition is likely to deteriorate Consequently at the preoperative examination the anæsthetist often finds a patient with a *high temperature* and a rapid pulse, as if he had a severe respiratory *infection* Ideally *one does not* like to anæsthetise any patient with a high temperature and who looks ill but if operation is postponed in the hope of improvement the patient continues to get weaker and the ideal moment for grafting is missed sometimes with disastrous results The correct management *of such a case* is to

MITRAL STENOSIS

MEDICAL knowledge has been built up largely by nicopathological correlations based on necropsy udies. But this method, however well it served our cestors, had many disadvantages. It only revealed the ate of affairs at the time of death, and the accompanying hysiological conditions had to be reconstructed by mple clinical observation supplemented by shrewd uess-work. The advent of cardiac surgery in mitral enosis has persuaded many physicians to adopt the bolder ethod of cardiac catheterisation in order to assess the hysiological effects of valve disease likely to be amenable o surgical treatment.

In Stockholm 49 cases of mitral stenosis have been arefully investigated in this way.[1] The patients were ubdivided according to degrees of breathlessness on ffort into four functional grades. By passing a catheter own the branches of the pulmonary artery to a point t which it occludes one of the subdivisions, a pressure record can be obtained which is probably the pressure in he pulmonary capillaries and which also reflects to ome extent the pressure changes in the pulmonary veins. This information, together with pressure records taken from the pulmonary artery and right ventricle, and also the cardiac output, gives a remarkably complete picture of the dynamics of the circulation. In groups 1 and 2, with little limitation of physical activity, cardiac output was normal and there was only slight abnormality n pulmonary arterial and pulmonary capillary pressures. In groups 3 and 4, with incapacitating dyspnœa, cardiac output was reduced and pulmonary arterial pressure was raised; while in group 4 pulmonary capillary pressure averaged 29 mm. Hg (close to the osmotic pressure of the plasma-proteins). In these two groups exercise increased the pulmonary capillary pressure to a level above the protein osmotic pressure at which œdema of the lungs could readily occur. In each functional group auricular fibrillation was associated with a lower average cardiac output than in the patients with sinus rhythm. A "diffuse" cardiac impulse was taken to indicate right ventricular hypertrophy, and in patients with this clinical manifestation the mean pulmonary arterial pressure was nearly always above 30 mm. Hg (normal 13 mm.). Other clinical signs said to indicate pulmonary hypertension (accentuated pulmonary second sound, pulmonary systolic murmur[2]) were found to be unreliable. The electrocardiogram was unreliable as evidence of *absent* right ventricular enlargement. Bifid P waves suggested hypertrophy of the left auricle, since they were associated with a high presystolic pressure wave in the pulmonary capillary pressure tracing. A loud apical systolic murmur was evidence of mitral incompetence, as indicated by a high systolic wave in the record of pulmonary capillary pressure, though sometimes pulmonary capillary tracings showed a high systolic wave in the absence of such a murmur.

Gorlin and Gorlin[3] have suggested a hydraulic formula for calculating the area of the mitral valve orifice; but the Swedish workers point out certain fallacies in this, particularly when the mitral valve is incompetent. In this connection it is interesting that Brock[4] holds that in mitral stenosis the mitral valve is nearly always oval-shaped and measures about 1 by 0·5 cm. This nearly standard size is encountered whether the symptoms are mild or severe; he holds that the fusion of the valves always takes place at the critical areas of insertion of the chordæ tendineæ, which are at the junction of the middle and outer thirds of the valve edges. If this is true, then we cannot picture the course of mitral stenosis as related to progressive narrowing of the valve; the varying clinical course in different types would depend on various physiological adaptations, perhaps determined by different effects of the rheumatic process on other valves and on different parts of the myocardium.

Another interesting point brought out by the Swedish investigators is the relatively slight increase in blood-content of the lungs even in the presence of high pulmonary vascular pressures. This agrees with the findings of Kopelman and his associates in this country[5] [6] and is possibly related to reactive narrowing of the pulmonary vessels.[7]

While the Swedish work lays an excellent practical foundation for further studies of mitral stenosis, it leaves many questions unanswered. Why do some patients develop such an extremely high pulmonary arterial pressure, which may reach or even exceed that in the systemic arteries? Why do those patients who develop massive left auricles or tricuspid insufficiency have such a relatively benign course?[8] If the stenosed valve orifice is of Brock's standard size, why are there such varied courses of different clinical severity? Closer study of the various subvarieties of mitral valve disease will be necessary, and each individual patient will be found to vary in some respect from his neighbour.

A NEW ANTIPRURITIC

THE best treatment of an itching dermatosis is to remove the cause; and to do so an accurate diagnosis and the choice of an appropriate remedy are essential. Unfortunately, there is as yet no specific treatment for a large number of pruritic conditions, which must be dealt with empirically and largely symptomatically. Of the older local antipruritics, many are messy or relatively ineffective, or they smell disagreeably. Local-anæsthetic ointments of the benzocaine class often sensitise the skin, and the contact dermatitis so provoked may become very severe before the doctor or the patient realises that it is being caused by the supposed remedy for the itching. Such a patient may be sensitised to related chemicals such as the sulphonamides, *p*-aminosalicylic acid, and hair dyes.

In the absence of a really effective antipruritic which can be given by mouth, we need good local applications of low sensitising power. N-ethyl-*o*-crotonotoluide, which is on the market in a vanishing-cream base, seems to be highly effective and relatively harmless. This compound was developed after the discovery that certain substituted crotonamides increased the "knock-down and kill" power of insecticides. It was found to have a potent action in vitro on rabbit itch-mites,[9] and extensive trials in human scabies gave excellent results.[10–12] During these trials, the application was shown to have a considerable antipruritic action, and this observation led to its use in non-parasitic itchy dermatoses.

Hitch,[13] who used 'Eurax,' a preparation of N-ethyl-*o*-crotonotoluide, on 200 patients suffering from a variety of skin disorders, said that over 75% found greater relief from this preparation than from any of the others previously used. The improvement in the itching was described as excellent or good in 65%. He had 4 patients who were sensitised by the application, but only one of them was affected by the active principle itself. Similarly, Peck and Michelfelder,[14] reported 1 case of sensitisation to N-ethyl-*o*-crotonotoluide in a series of 400 patients. A further case has been seen by Bereston,[15] in which

UNESCO tells how an observer from Mars, the objective scientist, views the human species What we want to know is how men come to view one another as they do. The fact, for example, that the relatively recent ancestors of present-day Scotsmen came from Ireland, Scandinavia, and France does not prevent Englishmen from recognising the Scots as a distinctive group (or from saying that "all Scotsmen are mean") Moreover, there are black Jews in Africa, yellow Jews in China, and every variety of white man among the Jews of Europe and America, so the "typical Jew" is different from country to country, and there can clearly be no "Jewish race" according to the canons of physical anthropology Nevertheless Jews are by and large a recognisable group of men marked by a common religion and common customs Ill-feeling towards such groups may be called racial prejudice, national prejudice, or cultural prejudice; but whatever its name it has very little to do with genetics or physical anthropology Thus we fear that the genetic approach to racial problems may do a disservice rather than a service to the cause UNESCO has at heart, because it hides the irrational basis of racial prejudice and pretends that it can be fought with scientific knowledge and reasoned argument The man who complains that all niggers smell is not interested in the scientific truth or otherwise of his statement, what he means is that he hates Negroes What has to be discovered is how he has come to feel such an emotion, and what are the circumstances which encourage its spread among his friends and neighbours

We are nearly all inclined to generalise about groups from single cases, and to view all foreigners with suspicion, even when they come from no further afield than Cornwall or Yorkshire We are prone to accept traditional judgments, like "the Irish are unreliable" or "the Italians excitable," because we believe we can recognise members of these groups at once by their speech and bearing, and often our experience bears out this belief In a few individuals this mild xenophobia becomes severe and pathological, and its origins require detailed case-histories to make them plain It is surprising how little psychiatric investigation there has been in the research on race prejudice To explain further how the virulent emotion of the few spreads at certain times and places to the whole community we must examine social conditions not only at the time of an outburst of violence but in the quiescent periods, and we must consider the reactions and motives of people who show no gross antiracial feeling as well as those of men who turn readily to lynching, the pogrom, and ritual murder Until this evidence has been collected we shall be unable to deal with racial prejudice other than empirically

HERPANGINA

FOR many years now a puzzling disease has reappeared in some areas of the United States each year during the summer or early autumn The illness, nearly always affecting children and generally those under 5 years of age, starts suddenly with fever, dysphagia, anorexia, sore throat, and pharyngitis, sometimes associated with vomiting and abdominal pain, usually it lasts 2–3 days Its most characteristic feature is the appearance in the mouth of a few greyish-white papulovesicular lesions, 1–2 mm in diameter and surrounded by an areola of erythema After 2–3 days these papules break down to give greyish-yellow ulcers which resolve after a few more days To this disease Zakowsky[1] gave the name herpangina, since it is somewhat similar to herpetic stomatitis Subsequent workers failed, however, to isolate the virus of herpes simplex The lesions in herpangina can be differentiated from those of herpetic stomatitis because they are limited to the anterior fauces, soft palate, uvula, and tonsils, while those of herpes are generally most pronounced on the buccal membrane and is often associated with fœtor oris, gingival hæmorrhage, and local lymphadenopathy Also herpangina occurs seasonally in small epidemics, whereas primary herpetic stomatitis is a sporadic disease rather more prominent in the winter[2]

Huebner and his colleagues[3] at Bethesda have now shown that herpangina is probably the most common manifestation of infection with the A group of the Coxsackie viruses In suckling mice, this group causes a diffuse myositis affecting predominantly skeletal muscles and not involving the brain, fat, or pancreas as the group-B viruses do Huebner and his associates surveyed a small community in the north west of Washington, D C, before, during, and after a small outbreak of herpangina for the presence of Coxsackie virus of the A group and for antibodies against six strains of Coxsackie virus, five of which had been isolated in cases of herpangina in this or neighbouring areas. The virus was found only in those people who had herpangina or were contacts of cases and in whom antibodies to the infecting strain developed The level of antibodies to the other strains causing herpangina elsewhere remained constant in both the infected and the uninfected people The Bethesda workers also showed that the infected group had no previous antibody to the infecting strain, whereas in the non-infected group the percentage of people with neutralising antibody was very high In infected households contacts with antibody in their blood did not have the disease or harbour the virus Thus the localisation of the epidemic was apparently due to the majority of the population being immune because of previous infection, for, although coming into contact with the virus, these people were protected by their circulating antibody, which was shown to keep the same titre for at least a year So far Coxsackie virus has been isolated from either the throat-washings or the fæces of 90% of the 50 cases of herpangina investigated, from 46% of contacts and from only 1% of the remainder of the population surveyed

Infection seemed to spread from case to case, the incubation period being 1–10 days Outbreaks were not explosive, as might be expected if the virus were spread by a vector such as food, drink, or infected flies Coxsackie viruses have been isolated from flies, and Melnick and Penner[4] have shown that the virus may survive, although not multiplying, in this host for as long as 14 days So far it is not known where the virus hibernates during the winter and spring Nor is it known how long it can survive in carriers, the longest time after initial infection that it has been found is 76 days These viruses are fairly resistant, and possibly if conditions were suitable they might survive outside the body and be taken up by man or some other vector and so initiate another small outbreak if introduced into susceptible households, sporadic cases of herpangina almost certainly go unrecognised, and probably they keep the infection alive in a community

Coxsackie viruses have been associated with poliomyelitis and other diseases, but often such isolations may have been due to chance At present it seems that the commonest manifestation of infection with the group-A Coxsackie viruses is herpangina, and that perhaps the chief syndrome due to the B group is Bornholm disease either in its typical or in its more non specific form There is some evidence, however, that occasionally Bornholm disease may be caused by group-A viruses also, although this disease might easily be wrongly diagnosed in cases of herpangina with abdominal pain and only a solitary lesion on the fauces

estimate the hæmoglobin level, to adjust to 100% or slightly more by blood-transfusion if necessary, and to anæsthetise the patient so that he may have his life-saving operation without delay.

Fig. 1 is the temperature, pulse, and respiration chart of a girl, aged 12 years, who sustained a 25% burn, 11% of which was full-thickness skin loss. In our experience such a child has a 90% chance of survival (Bull and Squire 1949), but without surgery she might well be in hospital for more than a year and perhaps succumb to added infection. The points of interest on this chart, which are typical of most severe burns, are as follows:

(1) The temperature did not settle to normal till a week after the second operation (about Dec. 30), when all the burned areas had been grafted and the grafts were nearly healed.

(2) The pulse-rate was still raised, even when the child was healed and discharged home; it will gradually return to its normal level.

(3) The respiration-rate never reached a level typical of a *severe respiratory infection.*

Most of the severe burns are dressed the day before operation, which provides an opportunity to examine the unbandaged chest. This child had her first operation on Dec. 6, having been dressed and checked as ready for operation on Dec. 5. Occasionally a patient develops a chest infection coinciding with the time of operation. If the infection is only developing on the day of operation, it has been found to be in the patient's interest to proceed without any postponement. Later, if the chest infection becomes fully developed, the burned areas are already covered with skin grafts. This is particularly important in the bigger burns of over 20% full-thickness skin loss, if the patients are to have a reasonable chance of survival.

TABLE I—THREE CASES IN WHICH ENDO

TRACHEOTOMY

Case no.	Age (yr.)	% burn	Area	Pr oper hæ gl		
1	4	13	Fronts of thighs, chest, and axilla	100·0%		
2	6	19	Trunk, thighs, and buttocks	97·5%	Yes	Yes
3	3	9	Whole arm up to shoulder	83·5%	Yes	Possibly but not essential

However, if the infection has already reached its height, there is no alternative but to postpone operation.

INDUCTION OF ANÆSTHESIA

Infants and children were all carefully premedicated so that they should have no unpleasant memories of their visit to the operating-theatre. Since they would all require several operations, efficient premedication was of the utmost importance. No child was ever subjected to the minor operation of a "cut-down" under local analgesia for setting up a transfusion in the ward before coming to the theatre. The mild vasodilatation produced by the anæsthetic almost invariably reveals previously hidden veins, and "cut-downs" can be avoided.

Anæsthesia was induced with nitrous oxide and oxygen, followed by trichloroethylene or with ether. A few patients in whom the premedication had not been perfect were given rectal thiopentone.

The passing of endotracheal tubes calls for particular care, because three children developed laryngitis and œdema of the glottis postoperatively of sufficient severity to require tracheotomy.

The details of the children are given in table I, which shows that none were burned over the glottis, and that only case 2 really required the passing of an endotracheal tube, because both buttocks were burned and she was required to lie prone. All three children received a mouth pack to make the tube airtight; possibly the presence of the pack may have influenced the severity of the postoperative laryngitis. Therefore, where possible, tubes are avoided, and the patients, especially children, are turned on the side only and not fully prone.

Adults.—Five years ago adults were induced with thiopentone and maintained on nitrous oxide and oxygen combined with trichloroethylene or ether or intermittent injections of thiopentone. In those days it was noticed that in major cases the blood-pressure would often sink to about 80/50 mm. Hg, even if the patient was being fairly adequately transfused. With the advent of new techniques combining pethidine, a muscle relaxant, thiopentone, and nitrous oxide and oxygen it is now possible to complete bigger operations

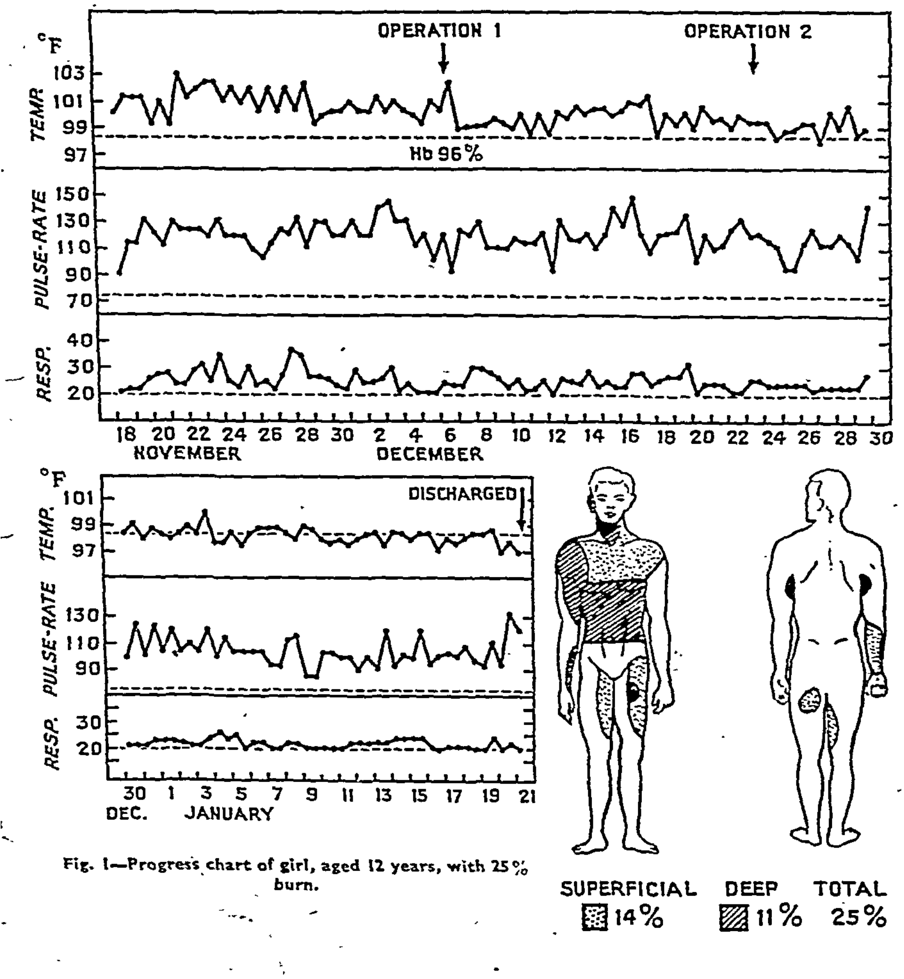

Fig. 1—Progress chart of girl, aged 12 years, with 25% burn.

But, though the ulceration is thus widespread throughout the colon, it in no way resembles that of ulcerative colitis, nor is the distribution alike Further, the condition more commonly attacks the ileum, and the burden of the argument has been that the ileal lesions associated with ulcerative colitis are only incidental It therefore seems unlikely that the two conditions are of the same parentage, their only similarity is that in Crohn's disease the colon may become ulcerated and the diarrhœa can be so severe that it simulates ulcerative colitis

Summary and Conclusions

The colon can be affected by three distinct conditions ulcerative colitis, ileocolitis, and proctosigmoiditis, all of which are customarily diagnosed as "ulcerative colitis"

It is suggested that ulcerative colitis is not a specific disease but a pathological state, behaving not unlike chronic ulcers of the leg The causes are to be looked for in the numerous primary conditions that initiate in the colon the degenerative process which is ulcerative colitis If the original trauma is severe, the case will pass directly into one of ulcerative colitis with continuous, though possibly abated, diarrhœa without remissions If healing with degenerate epithelium takes place, a latent interval, or "remission" will occur between the initial injury to the colon and the onset of ulcerative colitis, this form will be marked at first by remissions but later is likely to become chronic, with persistent diarrhœa In many instances the colon heals perfectly after damage by infection, stress, chemical agents, or whatever the cause may be, the patient is then spared from ulcerative colitis

The ileum is only involved in ulcerative colitis as a secondary phenomenon, either when the ileocæcal valve has become incompetent or, after operations that include an ileostomy, because of technical defects at the ileal stoma

Though Crohn's disease of the colon is more widespread than the gross changes suggest, it does not have any clear relationship to ulcerative colitis

I wish to thank Dr R St Johnston and Prof A P Thomson for permission to publish cases 1 and 2 respectively

PREVENTION OF POSTOPERATIVE CHEST COMPLICATIONS

Jacob Davidson
M B Edin, D A
CONSULTANT ANÆSTHETIST, LIVERPOOL REGIONAL HOSPITAL BOARD

The prevention of postoperative chest complications is still a very real problem, despite advances in their treatment It is agreed by most workers that the primary cause of such complications is impairment of respiratory movement following surgery, particularly, of course, abdominal surgery Churchill and McNeil (1927) demonstrated that one day after laparotomy the patient's vital capacity was half its preoperative value If it is assumed that the chief factor in this reduction is voluntary restriction of respiratory excursion, due to muscle spasm and pain arising from the site of incision, then one can confidently argue that if this postoperative pain is relieved or greatly diminished, a greater depth of respiration will be possible and thus increased aeration of the lung bases

Such an assumption is supported by the following report on 76 patients, all of whom had undergone upper abdominal operations, and in whom analgesia of the wound site was produced by intercostal block, using benzocaine (2%) and urethane (6%) to give prolonged analgesia This combination of drugs has been known to prolong analgesia for ninety days or even longer

Mode of Action

The rationale for this method is the chemical action which precipitates crystals of a drug in the tissues The crystals being relatively insoluble, they remain in situ, prolonging the action of the drug until absorption is complete In this instance urethane precipitates benzocaine crystals around the nerve, producing a long-acting analgesia Benzocaine, being almost insoluble, is made up in olive oil as a base The 6% urethane is in aqueous solution

Technique

At the end of operation, before the patient leaves the theatre, an intercostal block is carried out in the mid-axillary line, using 1 ml of benzocaine, followed by 1 ml of urethane, leaving the needle in position but changing the syringe For upper midline or paramedian incisions, a bilateral block of nerves T6–T10 is used, and for Kocher incisions, a block of T6–T12 on the right and T7–T9 on the left Accurate placing of the needle is imperative, for failure to block one nerve endangers the success of the whole procedure

A weak solution of benzocaine (2%) was used in order that the block should be purely sensory Walshe (1924) showed that weak solutions do not penetrate the neurilemmal sheath of the motor nerve, and therefore produce no motor paralysis The importance of this is obvious

The Patients

All these patients had been operated upon under general anæsthesia There were 60 cases of partial gastrectomy, 11 of perforated peptic ulcer, 3 of cholecystectomy, and 2 of gastro-enterostomy There was 1 death There were 5 failures or partial failures of the analgesia, due to incorrect placing of the block Apart from the death, there were no complications due to the analgesia—i e, sepsis, toxic absorption of the drug, or local necrosis

The effectiveness of the analgesia may be judged from the reduced number of doses of morphine required in the postoperative period (see table) Sedatives themselves often contribute to the production of chest complications An effort was made to select the cases for this procedure, for example, only those who had a definite pathological condition in addition to the disease for which the operation was performed, or who were considered likely to develop postoperative chest complications, were chosen This concurrent disease varied from simple obesity to chronic bronchitis and emphysema The ages ranged from 29 to 74 Those cases which are described in the table as having no preoperative concurrent disease were considered to be in poor physical condition, and therefore bad, or at the best only moderate, surgical risks There was no clinical evidence of pneumothorax in any of the cases

All the patients recovered from the analgesia The patient who died (case 64) remained quite well for twenty-four hours and free from pain She then developed signs of peritoneal irritation, and died seventy-two hours later Necropsy revealed a "blown" duodenal stump *It is interesting* to note that in this case the signs of peritoneal irritation did not arise until twenty-four to thirty-six hours after operation This may have been due to desensitisation of the parietal peritoneum by the block

In this connection it should be pointed out that attempts to eliminate the pain of peritonitis due to perforated peptic ulcer, using 2% benzocaine solution, Again the patient becoming shocked. Today the fraudque of nitrous oxide and oxygen analgesia comstilli with initial overventilation, as introduced by Brennan (1952), seems a good technique for the severely burned adult for the following reasons:

(1) The patient can be kept lightly anæsthetised and in possession of his protective vasomotor reflexes.

(2) He can tolerate an endotracheal tube and be turned prone without coughing.

(3) He wakes up almost immediately on completion of the operation.

(4) This greatly lessens the risk of any untoward occurrence in a helpless patient who is spreadeagled after the application of crêpe bandages and plaster-of-paris.

(5) Patients with burned faces and scalps can be intubated after the injection of pethidine, muscle relaxant, and thiopentone, without wearing a mask on the burned face.

MANAGEMENT DURING OPERATION

Blood-transfusion

During the grafting operation blood-transfusion is essential, and it is our practice for the anæsthetist to take charge of the drip. The aim is to have the blood drip running at the start of the operation and to replace any blood lost with an equal volume, or slightly more, from the transfusion. The scraping and excision of the sloughs from the burned areas often promotes a temporary rapid blood-loss; to cope with this it is generally necessary to increase the drip-rate by attaching a bellows to the air intake of the giving set and blowing air into the transfusion bottle.

A bellows used in this manner must be thoroughly clean; otherwise the blood itself will be contaminated. Since it is difficult to make sure that the inside of the bellows is sterile it is essential to fit a sterile air-filter between the bellows and the blood bottle (Bull and Hurst 1953).

The reason for scrupulous blood replacement as and when blood is lost is that, if the blood volume is allowed to decrease, the patient may become shocked and the systolic blood-pressure fall to 60 or 70 mm. Hg. While the surgeon is operating it is practically impossible to reverse this condition, even though blood be transfused rapidly, and there is no alternative but to stop the operation.

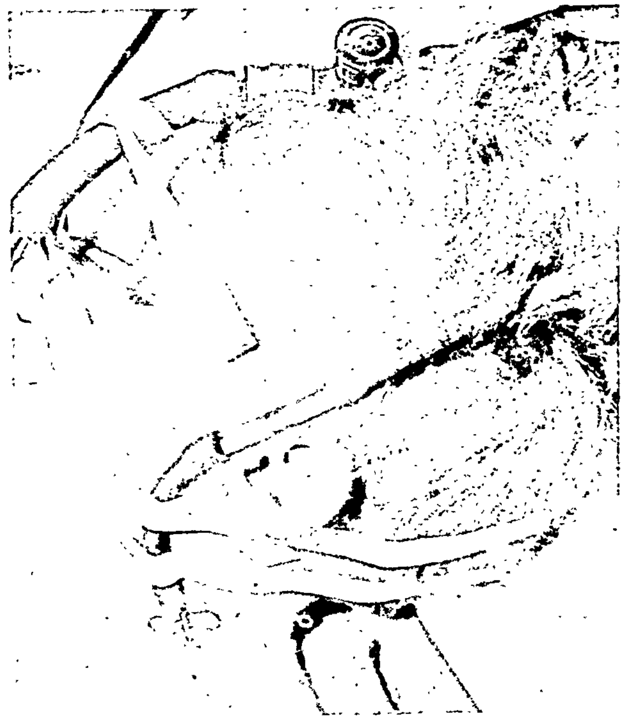

Fig. 2—External jugular vein being used for blood-transfusion.

Since the adoption of the practice of blood replacement in volumes equal to blood-loss it has become possible to cover larger percentages of burn at one operation; hence fewer operations are required to achieve full skin cover. This is very important; fig. 1 shows that it is only when the burn is completely grafted that the general condition of the patient begins to return to normal.

A convenient vein for transfusion is not always available. At the shock stage some veins have been used up by "cut-downs" on admission, and some patients are burned over their cubital fossæ, ankles, &c. However, a good standby on these occasions is often the external jugular vein (fig. 2). Whenever there is a dearth of convenient veins, or it is essential that a needle should not damage an awkwardly placed vein—e.g., the external jugular—the Guest (1941) cannula (fig. 3) is most useful. If only a quarter of an inch of vein is palpable, this cannula can be introduced with care and advanced an inch or more up the vein with safety.

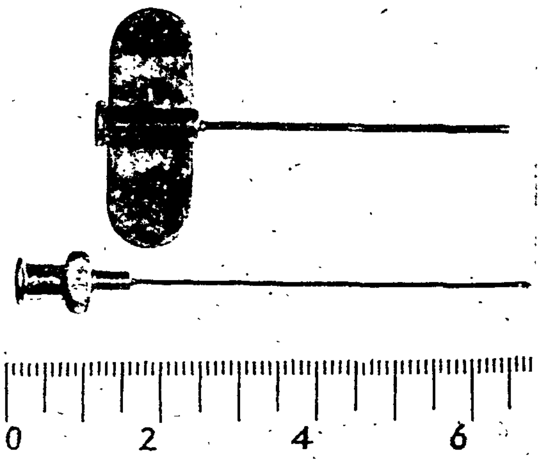

Fig. 3—Guest's cannula. Scale is in centimetres.

The use of hypotensive drugs was considered but not adopted. The policy has been not to interfere further with the already upset physiology and, if at operation blood is unavoidably lost in large quantities, to replace it with stored blood.

Collapse

In the last year three children collapsed during operation despite adequate blood-transfusion. All three showed a similar prodromal sign: cyanosis round the burns and widely dilated pupils, followed quickly by irregular respiration and then cessation and finally cardiac arrest. Details of these cases are shown in table II.

In all these cases the anæsthetic was discontinued at the first sign of any untoward occurrence and the lungs were inflated with oxygen. None of the patients were deeply anæsthetised, and all had spontaneous thoracic respiration before the sudden collapse. In cases 4 and 5 the lungs inflated easily at first but only with difficulty later when resuscitation was abandoned. Cardiac massage was done late on case 5 but promptly on case 6, who recovered. Cardiac massage seems to be the only satisfactory remedy, and it has to be early and by whatever method the surgeon is conversant with (Dark et al. 1952).

The general collapse associated with massive collapse of the lungs in cases 4 and 5 in table II may be partly explained as follows. All three children had fairly severe burns and scalds, and at the time of operation their injuries were several weeks old, during which time the were unsuccessful But the danger of masking of pain due to peritonitis may exist, and it is therefore advisable to watch for other clinical signs of peritoneal irritation

Results

Of those cases which were classified as failure or partial failure, 4 developed postoperative chest complications This represents 5·3% of the total, which compares favourably with recent figures of 6%, 8·9% (Langton Hewer 1943), and 10% (Lee 1947) All the other patients had complete analgesia of the site of operation and made normal recoveries

Other Uses of Benzocaine and Urethane

Ritchie Russell and Spalding (1950) have described the use of benzocaine and urethane in the treatment of painful amputation stumps It is now being used in various orthopædic conditions—e g, causalgias and fractured ribs—and for neuromata It has a particular use in the old patient with fractured ribs who often gets pneumonia and collapse, and it has been used as a prophylactic in such circumstances A patient who had continuous pain for several years from a developmental anomaly in the 5th left lumbar transverse process, making a false joint with the ilium, has been completely relieved for over ninety days

Summary and Conclusion

In a series of 76 cases of upper abdominal operations treated with long acting analgesics (benzocaine 2%, urethane 6%) the postoperative incidence of chest complications was 5·3% Its value in the prevention of these conditions is demonstrated Other uses for this long acting analgesic are also described Its effect may last for ninety days or more An additional advantage is that it is much less expensive than other long acting analgesics

I should like to thank the surgeons whose patients I treated in this investigation, and also the hospital dispensers for their help in preparing the solutions

LIQUID AIR FOR CASUALTIES IN MINES

THE EAST MIDLAND LIFE SUSTAINAER

A J G COULSHED
M Sc (Eng) Lond, M I Min E
DIVISIONAL RESCUE STATIONS MANAGER

J TREFOR WATKINS
M B Wales, D P H
DIVISIONAL MEDICAL OFFICER, NATIONAL COAL BOARD

IN coal-mining it is essential to have adequate means of rescuing and protecting people who have been or may be overcome by exposure to irrespirable atmospheres The equipment for this purpose should be easy to apply and easy to carry, for those who have to use it will already be weighed down by apparatus for their own protection

The apparatus in general use consists of cylinders of carbogen (93% oxygen, 7% carbon dioxide) fitted with suitable breathing masks But even the smaller pattern of this type weighs 32 lb and the carbogen supply lasts only twenty minutes There are therefore very substantial advantages, we believe, in our 'East Midland Life Sustainaer,' which weighs only 16 lb fully charged and affords protection for two hours without recharging

The purpose of this apparatus is to provide respiratory protection for asphyxiated men while they are still in an atmosphere polluted by toxic gases It is of simple design and comprises the following parts (see figure) *

---

* An application for a patent has been made by the National Coal Board

TABLE II—CHILDREN WHO COLLAPSED DURING OPERATION

Case no.	Age (yr.)	Injury	Premedication	Anæsthetic	Remarks
4	2	10% scald: chest, abdomen, right shoulder, and thigh	'Omnopon' gr. $^{1}/_{12}$, hyoscine gr. $^{1}/_{400}$	Nitrous oxide and oxygen, trichloroethylene	40 minutes after start of operation: less bleeding from donor area; cyanosis round burn; respiration irregular and ceasing after 30 sec.; cardiac arrest after further $1^{1}/_{2}$ minutes *Outcome.*—Death *Necropsy findings.*—Bilateral total collapse of lungs which in life had been healthy
5	$3^{1}/_{2}$	30% burn: chest, both legs, both arms, neck	'Nembutal' gr. 1, omnopon gr. $^{1}/_{12}$, hyoscine gr. $^{1}/_{400}$	Nitrous oxide and oxygen, ether, trichloroethylene, orotracheal tube size 2	45 minutes after start of operation: cyanosis at top of legs, followed by cessation of respiration and cardiac arrest 1 minute later *Outcome.*—Death (cardiac massage failed) *Necropsy findings.*—Bilateral total collapse of lungs which in life had been healthy
6	6	24% scald: trunk, thighs, axillæ, and back	Nembutal gr. 1, omnopon gr. $^{1}/_{6}$, hyoscine gr. $^{1}/_{400}$	Nitrous oxide and oxygen, ether	55 minutes after start of operation: cyanosis of chest round burn; respirations became irregular and ceased, together with cardiac arrest 8 minutes later *Outcome.*—Survived after cardiac massage for 15 minutes and is a normal child

general condition of each had deteriorated owing to the burn. Secondly, each was burned over the chest or trunk. In the preoperative period all had their chests bandaged, and probably the burns plus the dressings tended to limit full respiratory excursions. Part of the routine preoperative preparation is breathing exercises and blowing through bubble bottles; but, in spite of this, mucus may have collected in the lower bronchioles, and the child would then have come to the theatre with lungs susceptible to atelectasis. However, this is thought to be only a part of the problem, the remainder being still unsolved.

Bandages

At the end of the operation all the skin grafts have to be fixed in position with bandages. Many patients have burns of the trunk; hence both the chest and the abdomen are eventually swathed in crêpe bandage. In view of the danger of chest complications, either the chest or the abdomen is left loosely bandaged, and care is taken to ensure that the tightest part of the dressing exerts only firm pressure. On the discontinuation of the anæsthetic, with its high oxygen content, the patient occasionally becomes cyanosed, and if there is any reason to believe that this is due to inefficient aeration of the chest the bandages are removed and reapplied. Consequently it is our practice to retain any patient in whom both the chest and abdomen are bandaged for at least ten minutes after the anæsthetic has been discontinued. Any adjustments to bandages can be made at once instead of cutting the bandages as an emergency procedure in the ward.

TABLE III—EXAMPLES OF HEAT LOSS DURING OPERATION

Case no.	Age (yr.)	% burn	Duration of operation	Rectal temperatures (°F)		Decrease
				Start	Finish	
7	47	35	2 hr. 10 min.	101·8	95·4	6·4
8	3	35	2 hr.	100·7	93·0	7·7
9	$2^{1}/_{2}$	40	1 hr. 40 min.	103·4	95·3	8·1
10	7	37	1 hr. 15 min.	98·8	90·0	8·8

POSTOPERATIVE MANAGEMENT

Oxygen Tents

A feature of the skin-grafting operation for severe burns is that the patient lies on the operating-table almost completely uncovered for the duration of the operation. Since a patient becomes poikilothermic when anæsthetised, the body-temperature drops during the operation, and in several cases it has dropped to 90°F. Examples are shown in table III. This drop may be partly due to the amount and temperature of the transfused blood, which on occasion may be equal in amount to the whole blood volume and is always well below normal body-temperature. As consciousness is being regained and the patient is leaving the theatre, sometimes violent shivering develops as the body endeavours to recover its lost heat. If the operation has been extensive, the general condition of these patients may deteriorate considerably, and they become cyanosed in proportion to the violence of the shivering.

At the end of the operation these patients were dry and warm, their faces were pink, and they were showing no signs of clinical shock, because they had been adequately transfused. The rational treatment of the developing shivering and cyanosis is to aid the recovery of warmth by applying blankets, and to make up deficiencies in oxygen by placing the patient in an oxygen tent during the immediate postoperative hours—i.e., to treat the case as one of exposure to cold. This combination of warmth and oxygen on return to the ward prevents the shivering almost entirely, and no cyanosis develops. Patients treated in this way have a quiet and uneventful immediate postoperative period.

Nasal Feeding with Ryle's Tube

Sometimes a child may be too ill to take its food normally and require to be fed with concentrated fluid nourishment through a Ryle's tube.

Before the feeds are ever commenced one must be sure that the tube is in fact in the stomach and not in the trachea. There is only one infallible test, apart from radiography for proving that a Ryle's tube is in the stomach. If 5–10 c.cm. air is injected into the Ryle's tube while the ear or a stethoscope is placed over the left hypochondrium, there is an unmistakable loud rumbling noise.

Plasma Jaundice

Plasma jaundice occurs occasionally while the patient is undergoing a series of operations to cover the burn with skin grafts and to deal with contracture deformities. It used to be thought that thiopentone was metabolised in the tissues and not the liver; therefore it was not contra-indicated in jaundice. The following case suggests that this is not true:

A few years ago a man, aged 46, had had a 35% burn successfully treated, becoming healed in seven weeks. At this stage he developed plasma jaundice, and at the same time his left shoulder movements were very limited owing to the burn. A week later the shoulder was given a short manipulation under thiopentone 0·3 g. Ten hours later the patient recovered consciousness for a short while, and then succumbed to fulminating hepatitis thirty-six hours after the manipulation.

Swelling of the face occurred apart from œdema of the ankles, and was often associated with a rash, which was usually maculopapular, or a generalised erythema with intense pruritis

The occurrence of a sore mouth or ulceration of the buccal mucous membrane was in no case associated with a leucopenia This agrees with Kuzell's findings (1952) No case of agranulocytosis has occurred, and earlier reports (Etess and Jacobson 1953, Kuzell 1952, Stifel and Burnheimer 1953) suggest that it is a sudden event due to idiosyncrasy, and it is doubtful whether serial white cell counts will be of value in anticipating this complication Enlarged submandibular and cervical lymph glands were not necessarily associated with a sore mouth

4 patients complained of increasing dyspnœa, which stopped after withdrawal of phenylbutazone This has been attributed to the retention of water in the lungs or to pleural effusion In our series we had no positive evidence of this, but since then another patient has *shown small bilateral pleural effusions when taking* phenylbutazone, and, as suggested by Cudkowicz and Jacobs (1953), the presence of heart-disease may contra indicate the use of this drug

Hæmorrhagic complications have been reported by Rhys Davies et al (1952) Our patient with melæna was shown to have a gastric ulcer One other case had epistaxes Stephens et al (1952) noted a fall in platelets, although this was not associated with hæmorrhagic phenomena, and a prolonged clotting-time was demonstrated in 1 patient by Cudkowicz and Jacobs (1953)

Headache and dizziness were not severe, and did not necessitate the cessation of treatment

The dosage we employed in the series was usually 200 mg three times a day, but in some patients a smaller dose was effective, and it remains to be seen whether reduction in the dose will diminish the number of toxic effects

CONCLUSIONS AND SUMMARY

Phenylbutazone is an effective drug in the treatment of many cases of rheumatoid arthritis In a controlled trial, no change has been noted in the E S R , hæmoglobin, or white cell count If a beneficial effect is to be obtained at all, it is usually evident within two weeks

Toxic effects are common (40%), they usually occur early, and may cause treatment to be stopped (20% in our series) These are occasionally serious, and, in our opinion, peptic ulceration and renal or cardiac disease are contra-indications to the use of phenylbutazone

Because of its potential danger, phenylbutazone should only be given to patients under close medical supervision, and it is hoped that a less toxic substitute may be elaborated

We wish to thank Dr W S Tegner, physician to the department, for his advice and criticism in the preparation of this paper

The following case shows how an urgent operation complicated by infective hepatitis was done successfully :

Not long ago an epileptic boy, aged 12 years, had a fit and fell face down in the fire. His nose, one ear, mouth, and one eye were completely destroyed, and the eyelids of his second eye were affected by contractures and would not close. To prevent injury to his remaining eye it was necessary to repair the eyelids. Two weeks earlier he and his whole family had developed infective hepatitis. It was impossible to do the operation under local analgesia because of the septic burns round his mouth, nose, and head. The operation was successfully done under general anæsthesia using a modified Brennan's technique and no thiopentone.

After premedication with omnopon gr. $^{1}/_{6}$ and hyoscine gr. $^{1}/_{200}$ the patient was given intravenous pethidine 50 mg., and 2 ml. of 2% xylocaine was injected into the trachea and sprayed over the nares. While the patient was still conscious, a size-5 cuffed endotracheal tube was passed by blind intubation, because the scarred mouth would not admit a laryngoscope. After the injection of gallamine 60 mg. the patient was anæsthetised, and the anæsthesia was maintained by hyperventilation with nitrous oxide and oxygen throughout the operation, which lasted 70 minutes. A further 40 mg. of gallamine was required in divided doses.

MANAGEMENT OF THE AGED

Bull and Squire (1949) compiled tables from previous results which showed, for example, that a patient aged 80 with a 17% burn has a less than 5% chance of survival. This leads one to wonder if operation is worth while and whether the patient will tolerate a general anæsthetic. The answer to this problem appears to be that, provided the patient has not got congestive heart-failure concomitant with the burn, he is unlikely to die in the operating-theatre.

In the last five years forty-nine patients aged more than 70 who have survived about three weeks to be ready for grafting have been successfully anæsthetised without any death associated with the anæsthetic. One woman, at the end of operation and when the last bandage had been applied, collapsed suddenly and died from a large pulmonary embolus, but the remaining aged all returned to the ward having been given a further chance of life.

The induction of anæsthesia was similar to that described for younger adults, except that pethidine was never given in excess of 10 mg., nor was thiopentone given in excess of 0·15 g. Muscle relaxant and hyperventilation with nitrous oxide and oxygen were the main agents in keeping the patient very lightly anæsthetised. A cuffed endotracheal tube was always passed to maintain a scrupulously clear air-way and to enable endobronchial suction to be applied if required.

SUMMARY

The courageous acceptance of poor anæsthetic risks is necessary if extensively burned patients are to be saved.

Adequate blood-transfusion must accompany the operation and is best supervised by the anæsthetist.

Three unexplained collapses in children are described.

A burn is a big open wound, and its exposure *during* operation under general anæsthesia is associated with great heat loss.

An oxygen tent is an essential part of the postoperative facilities.

A technique for the management of a patient with plasma jaundice or infective hepatitis, who requires *urgent operation*, is suggested.

The aged patient who has survived a few weeks to be ready for skin grafting is a surprisingly safe anæsthetic risk.

My thanks are due to Mr. D. MacG. Jackson, surgeon in charge of the burns unit of the Birmingham Accident Hospital; my anæsthetist colleagues, Dr. L. J. Wolfson and Dr. D. J. Carter, for their most helpful criticism; and Mr. N. R. Gill and Mr. C. E. Richardson, of the photographic department of this hospital, for the photographs.

THE TREATMENT OF BULBAR POLIOMYELITIS IN CHILDREN

N. M. JACOBY
M.D. Lond., M.R.C.P.
PHYSICIAN, QUEEN ELIZABETH HOSPITAL FOR CHILDREN, LONDON; PÆDIATRICIAN, PEMBURY AND KENT AND SUSSEX HOSPITALS

IN poliomyelitis the issue of life and death does not usually depend on treatment. In bulbar poliomyelitis treatment is of paramount importance; and, although unfortunately recovery cannot be guaranteed, death will certainly ensue unless efficient and prompt treatment is given. Since the apparatus required is not usually to hand in a ward, and since bulbar poliomyelitis is relatively rare, perhaps when the emergency arises much time is lost in rushing about and searching for the various articles which are normally kept scattered about the hospital in different departments. Experience has shown that it is a great help to have the essential apparatus kept ready and for everyone to know what each has to do. It is hoped that this paper may help those who, not having had to deal with such a case before, are suddenly faced with the problem.

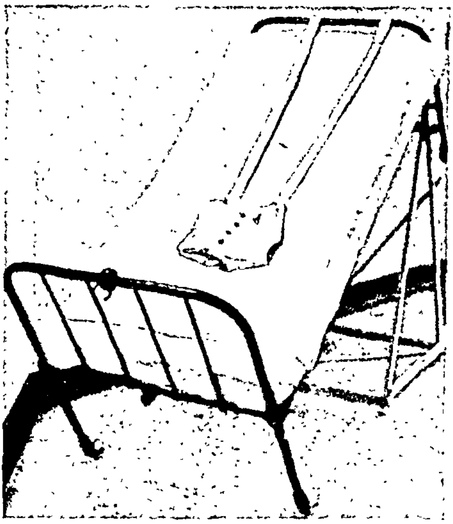

Fig. 1—Canvas jacket and webbing straps for suspending patient.

In our wards at Pembury and Tunbridge Wells we keep all the necessary small articles ready in a "Bulbar Palsy Box," which must not be used for any other purpose. The large heavy apparatus is sent for as soon as we know a child with poliomyelitis is to be, or has been, admitted.

APPARATUS REQUIRED

The apparatus required consists of the following items:

(1) Nuffield-Both respirator.
(2) Electric sucker.
(3) Jacques catheters of various sizes with additional side holes cut into the distal 1 in.
(4) Lengths of pressure tubing.
(5) Glass connection to join Jacques catheter to pressure tubing.
(6) Glass Y-piece to insert into pressure tubing.
(7) Canvas jacket with webbing straps (fig. 1).
(8) Tipping-frame 3 ft. 6 in. high (fig. 2).

It is important to make sure that the electrical apparatus has the correct "plug tops" and a sufficient length of cable to allow it to reach where it is proposed to work it. At least two "plug points" should be available.

It is not within the scope of this article to discuss the pros and cons of tracheotomy, which figures *so largely in*

TABLE I—SUBJECTIVE ASSESSMENT

—	Worse	No change	Slightly better	Much better	Total no of patients
Control group	4	12	7	4	27
Phenylbutazone group	4 (3 toxic)	2	8	14	28

Between control and drug groups $\chi^2 = 23.57$, $p < .01$

alterations in the diameter and range of movement of the joints

Our grades were

(1) Much better, meaning a definite improvement in the patient's symptoms and signs
(2) Slightly better
(3) No change
(4) Worse

The hæmoglobin, total white cell count and differential count, erythrocyte sedimentation rate (E S R) (Westergren), and weight were recorded before and after the trial

A larger group of 164 patients with rheumatoid arthritis was treated with phenylbutazone (200 mg three times a day or less) for periods of from one to six months Subjective improvement was assessed as in the controlled investigation Only when the subjective response was "much better" was the dose decreased below 200 mg three times a day

RESULTS

Controlled Investigation

5 patients failed to take the tablets for one month 3 in the drug group experienced toxic effects so severe that they were forced to discontinue phenylbutazone before final assessment, and are reported as "worse" Another patient failed to report because of domestic trouble, and 1 had bronchopneumonia

The subjective and objective assessments are shown in tables I and II The results of the special tests are shown in table III

Prolonged Treatment

The subjective assessment in the large group is shown in table IV 4 patients who were receiving corticotrophin or cortisone at the same time as phenylbutazone are not included, although 2 of them noted additional benefit from phenylbutazone

Toxic effects noted in this large group and their time of onset after treatment, are shown in table V Some patients experienced more than one toxic effect and are included in more than one column of the table

TABLE II—OBJECTIVE ASSESSMENT

—	Worse	No change	Slightly better	Much better	Total no of patients
Control group	3	19	3	2	27
Phenylbutazone group	5 (3 toxic)	11	3	9	28

Between control and drug groups $\chi^2 = 28.09$, $p < .01$

Anuria, which occurred in one patient and was associated with a sore mouth and swelling of the face, lasted thirty six hours and recovered spontaneously when phenylbutazone was withdrawn The urine showed no abnormality four days later A similar case was reported by Kling (1952)

Another patient was admitted to hospital with a history of three days melena After preliminary transfusion, partial gastrectomy was performed The stomach showed a chronic gastric ulcer half an inch in diameter on the lesser curve but no evidence of recent ulceration The patient gave no history of indigestion before taking phenylbutazone

More recently a man aged 72, died following five weeks' treatment with phenylbutazone (200 mg three times a day) Necropsy showed myocarditis, hepatitis, and tubulo interstitial nephritis (This case is being reported in detail separately)

DISCUSSION

The assessment of improvement in rheumatoid arthritis, particularly with a new drug, is notoriously difficult This is emphasised by the fact that, in the controlled series, all the patients were deprived of their usual analgesic drugs, and yet out of 27 subjects in the control group, 11 claimed to be improved

Other workers have advocated the use of the joint tenderness test in the assessment of objective improvement We have found it difficult to standardise the pressure exerted on the joint, and have found the patients' response inconstant and therefore unreliable We have, therefore, continued to use measurement of joint movements and size, and performance tests in assessing objective improvement

TABLE III—CHANGE IN WEIGHT, HÆMOGLOBIN, WHITE CELL COUNT AND ERYTHROCYTE SEDIMENTATION RATE IN PATIENTS TAKING PHENYLBUTAZONE

Weight

—	Mean weight before trial (lb)	Mean change in weight after 2 weeks (oz)	Level of significance	Mean change in weight after 4 weeks (oz)	Level of significance
Control group	133·7 (±25)	−10 (±27·7)	p < 0·01	−6 (±61·2)	p < 0·01
Drug group	144·4 (±20)	+53 (±52·8)		+42 (±47·2)	

Hæmoglobin

—	Mean value before trial (%)	Mean change after 4 weeks (%)	Level of significance	
Control group	80·7 (±10·4)	+2·5	0·2 > p > 0·1	p ≏ 0·02
Drug group	82·3 (±17·9)	−3·2	0·1 > p > 0·05	

White-cell Count

—	Mean value before trial (per c mm)	Mean change after 4 weeks (per c mm)	Level of significance
Control group	7970 (±842)	−376	Not significant
Drug group	8050 (±1024)	−379	

Erythrocyte sedimentation Rate

—	Mean value before trial (mm per hr)	Mean change after 4 weeks (mm per hr)	Level of significance	
Control group	14 (±20·1)	−14·5	p > 0·01	p > ·01
Drug group	41·1 (±19·5)	+3·1	0·5 > p > 0·4	

Standard deviations in brackets

The number of patients showing subjective and objective improvement is significantly greater in the phenylbutazone group than in the control group ($p < 0.01$)

The patients in the control series were comparing their tablets with other analgesic drugs (usually compound codeine tablets *B P*) and a large number found phenylbutazone in this dosage better than codeine tablets

TABLE IV—FOLLOW UP OF PATIENTS TAKING PHENYLBUTAZONE OVER PERIODS UP TO SIX MONTHS

Length of follow up	Total no of patients	Much better	Slightly better	No change	Worse or stopped for toxic effects
1 month	164	72 (44%)	43 (26%)	27 (16%)	22 (13%)
2 months	134	65 (45%)	26 (20%)	24 (18%)	19 (14%)
3 months	115	50 (44%)	20 (17%)	21 (18%)	24 (21%)
4 months	86	37 (43%)	14 (16%)	15 (17%)	20 (23%)
5 months	47	25 (53%)	3 (6%)	10 (21%)	9 (20%)
6 months	18	9 (50%)	—	4 ([illegible])	5 (28%)

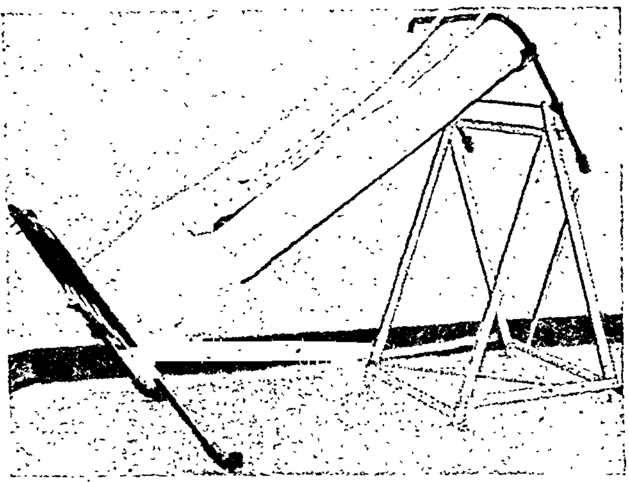

Fig. 2—Wooden frame for tipping bed.

American reports. Suffice it to say that it appears to be unnecessary. The use of positive-pressure artificial respiration has also been recommended recently, but it must be remembered that the apparatus is expensive and very few hospitals have it, whereas the Nuffield-Both respirator is to be found in practically every hospital in this country. Everything required for the treatment suggested here is normally found in hospitals or can be made in them at small cost.

TREATMENT REQUIRED

The paralyses which require treatment in bulbar palsy are those affecting deglutition and respiration. Paralysis of deglutition prevents the intake of food and drink, but because of its limited duration this is of minor importance compared with the inability to swallow saliva and nasopharyngeal and pulmonary secretions, which are consequently inhaled and drown the child. The result of respiratory paralysis is obvious. The treatment to overcome these paralyses can be listed as follows:

(1) Tipping.
(2) Suction.
(3) Artificial respiration.
(4) Feeding.

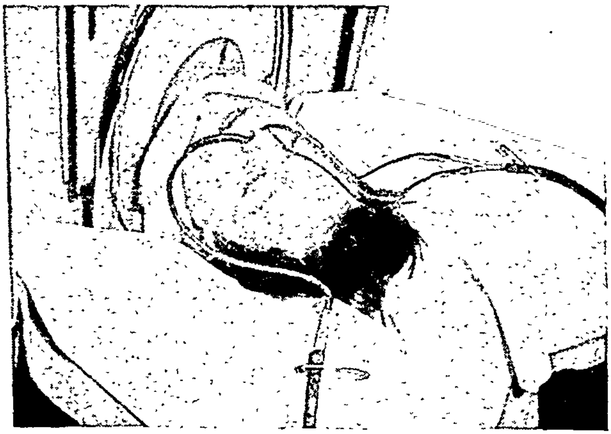

Fig. 3—Large Jacques catheter, used for suction, in left nostril, and oxygen catheter in right nostril.

Tipping

With the patient lying on his back, the trachea runs posteriorly at an angle of about 20°; hence to reverse this the angle of tip must be greater than 20°. If the trachea were simply a tube, any angle above 20° would allow fluid to run out of it; but in practice air is drawn into the trachea more forcibly than it is expelled, and in the Both respirator the difference is considerable. Therefore to prevent fluids from being inhaled the angle of tip needs to be about 40°; this means that the foot of the bed has to be about 3 ft. 6 in. higher than the head. To effect this we use a simple wooden frame (figs. 1 and 2). In an emergency, hospital furniture can be used instead.

Suspending the patient.—When a child is tipped to an angle of 40°, secure suspension provides something of a problem. Originally we used lengths of 6-in. bandage, with cotton-wool over the points of pressure, but the sense of insecurity to both patient and staff was considerable. We now use the canvas jacket with webbing straps (made in the hospital workrooms), and this has proved satisfactory and can be used both on a bed and in the respirator.

The child is always laid on its back, and though, from the point of view of angle of tip, a much lesser degree would be required if it lay on its face, we have found in practice that the weight of the body pressing on the chest and abdomen makes respiration almost impossible, and we have had to abandon the position whenever we have tried it.

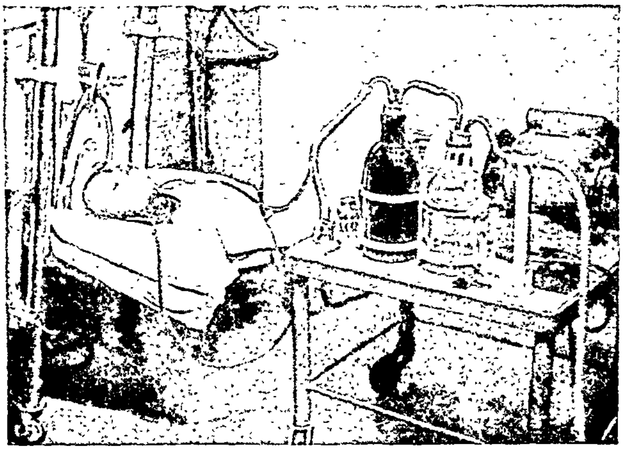

Fig. 4—Patient connected up, through catheters and rubber tubing, with powerful suction plant.

Suction

It is impossible to overemphasise the importance of efficient suction. Much of the secretion is saliva, which is easily removed; but there is also a good deal of thick tenacious mucus, which only a powerful electric sucker will remove. Our practice is to pass the largest possible Jacques catheter (fig. 3) down the nostril for 2 or 3 in. Some force may be required. The catheter is connected by pressure tubing to the sucker (fig. 4), but at some point the tube is broken for the insertion of a Y-piece (fig. 5). Thus suction can be turned on and off at will by closing the open limb of the Y-piece with the thumb. Rapid intermittent suction for periods for $^1/_2$–1 minute, at intervals of about 10 minutes, will remove all secretions very well.

Artificial Respiration

A large proportion of patients with bulbar poliomyelitis develop respiratory paralysis and have to be transferred to a respirator. A constant watch must be kept on them because the paralysis may develop with dramatic suddenness. As soon as this happens the child is put in the

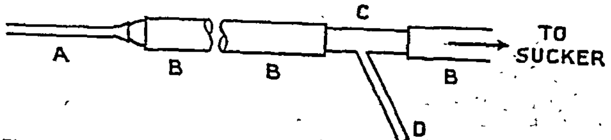

Fig. 5—Method of control of suction: A, Jacques catheter; B, pressure tubing; C, glass Y-piece. By closing Y-piece with thumb at point D, pressure of suction can be controlled.

TABLE V—COMPLICATIONS WITH TIME OF ONSET

—	Week of treatment							Total	No stopping treatment
	1	2	3	4	5	6	6 +		
Diarrhœa	5				1			6	1

Vertigo	1	1	1					3	3
Epistaxis			1					1	0
Malaise	1					1		2	2

Total no of patients 164
Total no with complications 67 (40 8%)
Total no stopping treatment 33 (20%)

Steinbrocker et al (1952) have found phenylbutazone more effective as an analgesic than salicylate, amidopyrine, or gentisate Currie (1952) reported subjective and performance improvement in 92% of cases with rheumatoid arthritis treated with phenylbutazone intramuscularly, while Rhys Davies et al (1952) performed a controlled experiment with 32 patients, using phenylbutazone intramuscularly, and reported a considerable difference between the groups treated with saline and with phenylbutazone Using smaller numbers of patients, with no control groups, Dudley Hart and Johnson (1952) reported improvement in 81% of patients

In our large series we found that 70% showed subjective improvement in a follow-up period of one month, a figure lower than that reported by these observers, and agreeing more with Stephens et al (1952) and Steinbrocker et al (1952) This figure became less with a longer follow-up period, until only about half the patients were still benefited at the end of six months

Objective improvement has been reported by other authors, we found it in 11 out of 27 patients (40%) This is less than the number reported by Rhys Davies et al (1952) The difference may be accounted for partly by the length of the trial period Some patients experienced transient benefit which wore off before the end of the trial

Kuzell et al (1952) have suggested that patients suffering from psoriasis associated with arthritis may derive benefit from phenylbutazone We have treated 7 such patients In only 1 was there a slight improvement in the skin condition, although the joints were improved in 3

There was no significant change in the hæmoglobin, white-cell count, or E S R in those treated with phenylbutazone in the controlled series The fall of the mean E S R in the control group remains unexplained, and did not parallel any change in the clinical condition of these patients

Minimum perceptible erythema times were estimated by Partington (1952) on this controlled series and showed no alteration

A fall in the hæmoglobin level was reported by Stephens et al (1952), while Currie (1952) reported a fall in the E S.R of patients taking phenylbutazone We could not confirm these findings

The phenylbutazone group show an average gain in weight at two and four weeks, which is statistically significant ($p<0\ 01$) An increase in weight has been shown to be due to a retention of water and sodium (Green and Williams 1953, Wilkinson and Brown 1953)

Toxic Effects

The toxic effects in this series have been similar to those already reported, and occurred in 67 (40%) out of 164 cases In half the cases the toxic effects wore off, although the drug was continued

Swelling of the face occurred apart from œdema of the ankles, and was often associated with a rash, which was usually maculopapular, or a generalised erythema with intense pruritus

The occurrence of a sore mouth or ulceration of the buccal mucous membrane was in no case associated with a leucopenia This agrees with Kuzell's findings (1952) No case of agranulocytosis has occurred, and earlier reports (Etess and Jacobson 1953, Kuzell 1952, Stifel and Burnheimer 1953) suggest that it is a sudden event due to idiosyncrasy, and it is doubtful whether serial white cell counts will be of value in anticipating this complication Enlarged submandibular and cervical lymph-glands were not necessarily associated with a sore mouth

4 patients complained of increasing dyspnœa, which stopped after withdrawal of phenylbutazone This has been attributed to the retention of water in the lungs or to pleural effusion In our series we had no positive evidence of this, but since then another patient has shown small bilateral pleural effusions when taking phenylbutazone, and as suggested by Cudkowicz and Jacobs (1953), the presence of heart-disease may contra-indicate the use of this drug

Hæmorrhagic complications have been reported by Rhys Davies et al (1952) Our patient with melæna was shown to have a gastric ulcer One other case had epistaxes Stephens et al (1952) noted a fall in platelets, although this was not associated with hæmorrhagic phenomena, and a prolonged clotting-time was demonstrated in 1 patient by Cudkowicz and Jacobs (1953)

Headache and dizziness were not severe, and did not necessitate the cessation of treatment

The dosage we employed in the series was usually 200 mg three times a day, but in some patients a smaller dose was effective, and it remains to be seen whether reduction in the dose will diminish the number of toxic effects

CONCLUSIONS AND SUMMARY

Phenylbutazone is an effective drug in the treatment of many cases of rheumatoid arthritis In a controlled trial, no change has been noted in the E S.R, hæmoglobin, or white cell count If a beneficial effect is to be obtained at all, it is usually evident within two weeks

Toxic effects are common (40%), they usually occur early, and may cause treatment to be stopped (20% in our series) These are occasionally serious, and, in our opinion, peptic ulceration and renal or cardiac disease are contra-indications to the use of phenylbutazone

Because of its potential danger, phenylbutazone should only be given to patients under close medical supervision, and it is hoped that a less toxic substitute may be elaborated

We wish to thank Dr W S Tegner, physician to the department, for his advice and criticism in the preparation of this paper

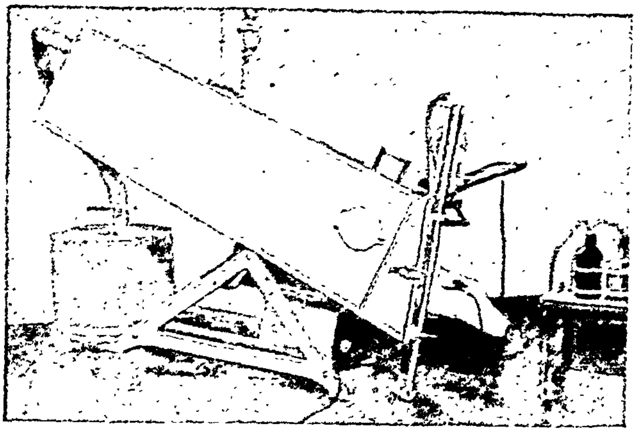

Fig. 6—Respirator tipped to required degree. Note blocks under one foot of stand.

respirator, which must now be tipped to the required degree (fig. 6). It is important that the canvas jacket should also be used in the respirator; otherwise the child's weight will be carried by the shoulders pressing against the lid of the box, and this causes great pain.

Feeding

For the first 24–48 hours we have found it best to make no attempt at feeding, but simply to make good the loss of fluid with a rectal drip of 5% dextrose in N/5 saline solution. After this period the child can usually swallow small amounts by mouth, or tube feeding can be used.

COMMENTS

This treatment has now been used on seven children aged 4–13 years. Six of them recovered. The duration of treatment averaged about seven days. In the children who survived, residual paralysis was less than might have been expected. All the children had rhinolalia, which recovered within a year. Five children had diaphragmatic paralysis: one died, and in the others function returned. Two children had a sternomastoid paralysis which recovered within two years, and 2 had moderate paralysis of one upper limb, with almost complete recovery of function. One child had gross paralysis of both upper limbs, and another had gross paralysis of all four limbs. These last two children made only a slight recovery of function.

I wish to thank Dr. L. Sagorin and Dr. S. Jarvis for their help in treating these cases; and my E.N.T. colleagues Mr. J. V. Clark and Mr. N. Asherson for refusing to do tracheotomies.

WHAT IS ULCERATIVE COLITIS?

B. N. Brooke
M.Chir. Camb., F.R.C.S.
READER IN SURGERY IN THE UNIVERSITY OF BIRMINGHAM

The cause of ulcerative colitis has eluded us, and it is my belief that there are two reasons for this. First, the diagnosis of ulcerative colitis has been applied to patients with chronic or recurrent diarrhœa, which, apart from Crohn's disease (which will be considered later) can be caused by three different diseases, of which only one should be termed ulcerative colitis. Secondly, this true "idiopathic" ulcerative colitis is probably not a specific disease entity so much as a pathological state arising from damage to the colon by a number of different agents.

Causes of Chronic Ulceration of Colon

The three conditions which give rise to chronic ulceration of the colon and thus chronic diarrhœa are indicated in fig. 1.

(1) *True "idiopathic" ulcerative colitis* affects the sigmoid and descending colon maximally—though this is not to say that it starts there—extends downwards into the rectum and proximally to a variable distance; it stops abruptly at the ileocæcal valve, except when the disease has been present long enough to damage the structure of that valve and render it incompetent (see below). This is, therefore, a primary colitis—primary in the sense that the colon is the organ primarily involved.

(2) "*Right-sided*" *colitis* is almost certainly a secondary colitis, in which the ascending and adjacent transverse colon are involved initially, while the bowel beyond remains radiologically normal (fig. 2) but *not* always sigmoidoscopically so. In the later stages the whole colon is involved. The colonic changes are secondary to an ileitis which may be difficult to detect by barium studies but is sometimes indicated by a defect of fat-absorption (Brooke and Cooke 1951). A comparison of the radiographs (fig. 3) and anatomical specimen (fig. 4) shows this difficulty in case 1:

Case 1.—A man, aged 40, had had diarrhœa for as long as he could remember, with four or five soft bulky motions daily, increasing in recent years to double that number, while the stool became more watery, presumably as the secondary colitis advanced. He eventually developed a carcinoma in the transverse colon.

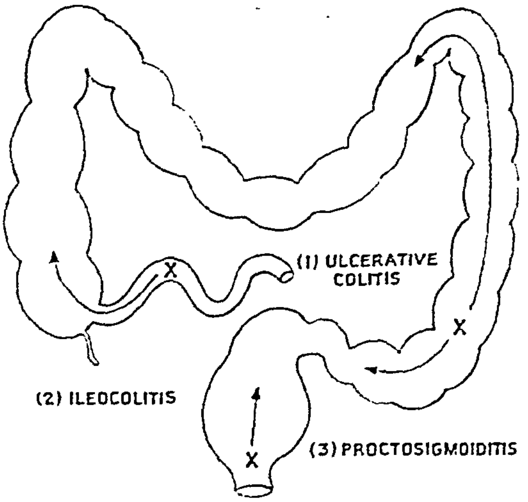

Fig. 1—The three conditions which cause chronic ulceration of colon and chronic diarrhœa.

The small bowel in enterocolitis or ileocolitis, as this condition should be called, is involved over a considerable distance—in case 1 from the lower part of the jejunum onwards, with small shallow ulcers and intervening mucosal œdema. The recognition of ileocolitis is rendered more difficult by the fact that on external examination of the ileum—e.g., at laparotomy—no abnormality may be detected, and in this respect, as in the appearance of the ulceration, ileocolitis is unlike Crohn's disease.

Case 2.—A woman, aged 24, who had had diarrhœa and right-sided abdominal pain for 3 months, was submitted to laparotomy because vomiting, abdominal distension, and an increase of pain suggested a perforation supervening on ulcerative colitis. At the time of her admission she was passing five motions by day and five at night. Though her rectum appeared normal at sigmoidoscopy, the cæcum and colon were seen to be thickened and red at laparotomy: no perforation was found, and the ileum appeared normal. However, at necropsy 10 days later the jejunal mucosa was swollen and hyperæmic and the ileum had shallow ulcers of irregular distribution throughout its length, with partial healing in some places.

In this case severe and acute enterocolitis was accompanied by fatty degeneration of the liver: *this change seems to be a constant finding in ileocolitis or enterocolitis* and was present also in case 1.

That the ileocæcal valve is intact in ileocolitis is an indication that the ileitis is not due to a "flowback"

FATAL AGRANULOCYTOSIS AND GASTRIC ULCERATION DUE TO PHENYLBUTAZONE

NANCY V DILLING
M B Lpool
RESIDENT CLINICAL PATHOLOGIST, ROYAL LANCASTER INFIRMARY

THE value of phenylbutazone (1 2 diphenyl-3 5-dioxo-4-*n*-butylpyrazolidine, 'Butazolidin') in giving symptomatic relief in rheumatoid and other forms of arthritis has been established since its introduction by Currie in 1952 Its comparatively simple structure, related to that of amidopyrine, has stimulated large scale production , and the drug is now widely used, sometimes perhaps without full awareness of the risks In the past month 2 cases of agranulocytosis attributable to phenylbutazone have occurred in this area, one terminating in death This case is described here

CASE-HISTORY

The patient, a woman aged 53, had suffered from rheumatoid arthritis for seventeen years , although her deformities were crippling, she had not had any treatment other than physiotherapy and mild analgesics of salicylate type She was not known to have any disorder of the cardiovascular or alimentary system, and had never had an allergic reaction

At the request of the patient and her relatives, her family doctor agreed to try a course of phenylbutazone On March 13 this year treatment was begun with 600 mg daily by mouth. After five days of therapy œdema of the legs and arms developed , treatment was suspended, and the œdema subsided rapidly during the next forty eight hours Seven days later therapy was recommenced, but the dosage was reduced to 400 mg daily After three days the patient complained of epigastric pain and diarrhœa, and she vomited some bloodstained fluid Next day she had a sore throat and dysphagia

A day later (April 2) the patient was admitted to hospital She was found to have ulceration of the pharynx and a temperature of 104 8°F Examination of the blood showed absolute agranulocytosis, the white cells being made up of 1440 lymphocytes and 60 monocytes per c mm In addition there was severe anæmia, with hæmoglobin 8 g per 100 ml (51%) and red cells 3,300,000 per c mm No other significant symptoms or physical signs developed, and the patient died in coma three days after admission

Necropsy Findings

The necropsy was done forty eight hours after death, during which time the body was refrigerated

Pharynx and œsophagus—The pharynx was extensively ulcerated, and the œsophagus showed œdematous thickening of the wall with destruction of the surface epithelium throughout the whole length Microscopic examination of the œsophagus showed complete replacement of the squamous epithelium by eosinophilic amorphous material, while the subepithelial layer of connective tissue contained young fibroblasts which extended into the muscle coats, separating the individual muscle fibres There was pronounced round cell infiltration of all coats, but neutrophil polymorphs were not present

Stomach—In the stomach there were about a hundred superficial ulcers ranging 1–5 mm in diameter These lay in parallel rows in the long axis of the stomach, and most of them situated on the ridges of the gastric rugæ Unlike acute gastric erosions the ulcers were craterous, heaped up inflamed mucosa surrounding a small central area of necrosis Microscopically the base of each ulcer was formed of amorphous eosinophilic material overlying an area of submucosa heavily infiltrated with young proliferating fibroblasts Around the periphery a dense ring of lymphoid tissue beneath the mucosa explained the macroscopic appearance of the elevated and swollen mucous membrane surrounding the ulcer pits Neutrophil granulocytes were not found in the sections No other lesions were found in the alimentary canal

Spleen—The spleen was enlarged (200 g) and pale, but otherwise normal macroscopically Microscopically the splenic pulp was largely replaced by loose fibrous tissue containing very few cells and while there were a few lymphoid aggregations, true malpighian corpuscles were not evident The vessels were normal This medullary endothelial proliferation was probably part of the chronic rheumatoid arthritis syndrome, and not a result of phenylbutazone therapy

Lungs—Both lower lobes were grossly œdematous and congested The alveoli were œdematous and many were packed with red blood cells There was no inflammatory reaction

Knee joint and femur—The articular surface of the right knee joint showed gross destruction of the type seen in active rheumatoid arthritis The marrow of the femur contained confluent erythroblastic foci in the head and upper third of the shaft

DISCUSSION

The commonest complications of treatment with phenylbutazone have been generalised œdema, digestive disturbances, skin eruptions, granulopenia, and hæmorrhage from the gastro intestinal tract Rarely jaundice has been reported, and a fall in the platelet-count has been noticed in a few cases

Œdema

Currie's (1952) original series of 81 cases, in which 1 g of phenylbutazone was given daily for ten days, included none in which œdema developed, but of 100 cases treated by Davies et al (1952) with 1 g daily 8 developed œdema of the legs , while Kuzell et al (1952) found œdema in 17 out of 140 cases treated Both groups of workers report that the œdema subsided rapidly within two days after either reducing the dosage or restricting sodium intake Green and Williams (1953), in a study of healthy volunteers, constantly found that between the second and eighth hour after injection of 1 g of phenylbutazone there was a reduction in urinary output associated with a fall in urinary sodium It seems therefore that sodium retention results directly from phenylbutazone medication, and that œdema indicates overdosage rather than idiosyncrasy Green and Williams also observed that the phenylbutazone level in the blood, though high soon after injection, fell rapidly in the next forty eight hours, and was undetectable after ninety-six hours Hinz et al (1953), however, found in a case of agranulocytosis which had resulted from treatment with 400 mg of phenylbutazone by mouth daily for forty six days that traces of the drug persisted in the plasma fifteen days after administration was discontinued

Gastro intestinal Tract

Bleeding from the gastro intestinal tract has been reported (Dudley Hart and Johnson 1952, *British Medical Journal* 1952, Ross and Baldwin 1953, Benstead 1953) In this total of 7 cases, 2 of which were fatal, each of the patients received the drug by mouth Of the cases reported by Dudley Hart and Johnson (1952) 1 developed bleeding from an acute duodenal ulcer two days after starting a third course of 800 mg of phenylbutazone daily , and in the other 2 cases melæna appeared after four weeks' and after two days' treatment Ross and Baldwin (1953) report melæna after three weeks' treatment with 400 mg daily, and hæmatemesis after administration of 1 g daily for seven days

Of the 2 cases in which the patient died, 1 was in a woman of 65 who had received 600 mg orally each day for fifteen days (Benstead 1953) She developed hæmaturia and died next day The stomach was normal but at the lower end of the œsophagus there was an ulcer 1/ in in diameter, and in the duodenum a subacute ulcer 1/4 in in diameter which had perforated and caused general peritonitis In the other case a woman of 75 had received 1200 mg of phenylbutazone daily for eight days, when massive hæmatemesis supervened (*British Medical Journal* 1952) At necropsy the stomach contained multiple superficial ulcers 1–2 cm in diameter, mostly in the fundus

In none of these accounts is it suggested that the gastro intestinal lesions were other than acute, and in none is any previous dyspepsia mentioned

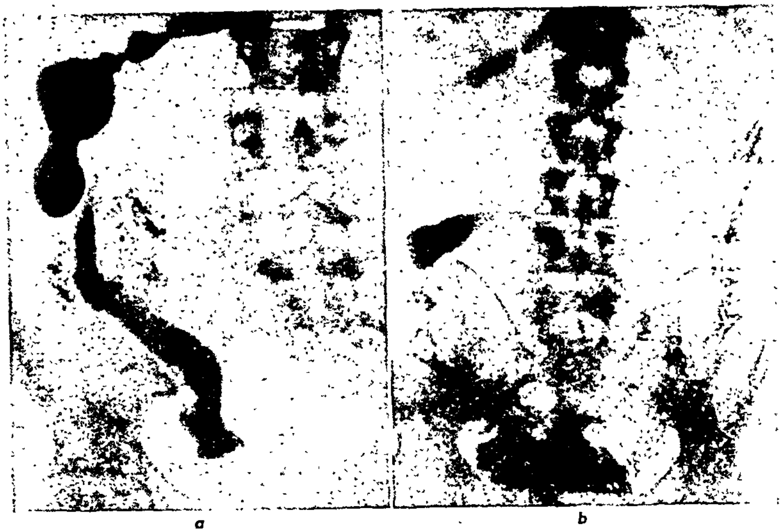

Fig. 2—Radiographs from a man, aged 33, with diarrhœa (6 motions daily) and defective fat-absorption : a, after barium meal to show ileal involvement ; b, after barium enema to show colonic involvement.

of infected material, in contrast to the ileitis associated with ulcerative colitis. Though clinical recognition of the one disease from the other is difficult, one point in the history is of value. Whereas ulcerative colitis tends to fluctuate between remission and recrudescence in its earlier stages, only to become continuous later when the bowel is so utterly destroyed that no attempts at healing can take place, in ileocolitis these fluctuations are less well defined and, indeed, no remission may occur at all. In its commonest form ileocolitis starts with four to eight soft motions daily, not always containing pus, and this continues ; in ulcerative colitis the onset of an attack of diarrhœa is usually sudden, with ten, fifteen, or even twenty fluid fæcal motions daily, containing pus and blood, and during the intervals of remission the motions may be normal in character and frequency.

(3) *Proctosigmoiditis* is better recognised but seldom referred to. Hess Thaysen (1934) gives an excellent account of it and states that Strauss gave the first description in 1910. As Thaysen points out, it is thought by some to be a subgroup of the more usual form of ulcerative colitis, a view not well substantiated by the facts. A mild chronic intractable inflammation is to be seen in the lowermost reaches of the rectum ; its upper limit is often sharply defined, the area involved being no more than the last 2 or 3 inches of the rectum, and less often its distribution in the rectal ampulla is patchy. In the earlier stages no frank ulceration is to be seen, though the mucosa is inflamed and bleeds if touched, this general appearance suggesting the name, sometimes applied, of granular proctitis. It presents in various ways as " bleeding piles," as diarrhœa, and even through anæmia, which is the only general disturbance associated with the disease. Though diarrhœa can be the patient's complaint it is spurious, for proctosigmoiditis is associated with constipation ; it is the blood and pus collecting in the rectum and passed in several fluid motions, notably earlier in the day, which give rise to the complaint. The condition is singularly indolent ; it may remain localised for years or gradually pass upwards into the sigmoid ; it is at this stage of proctosigmoiditis that ulcerative colitis is simulated, particularly since anal fissures and fistulæ complicate both conditions. One example indicates the degree of constipation in these patients :

Case 3.—A woman, aged 34, who had had proctosigmoiditis for 7 years was submitted to surgery because of chronic severe secondary anæmia (Hb 41%, red cells 2,900,000 per c.mm.), tenesmus, and an anal fistula which would not heal after excision. Since colostomy might have precipitated trouble higher in the colon, ileostomy was performed, but not before it was noted that barium was still present in the colon 3 weeks after a barium enema. 3 months after ileostomy, when the large bowel was excised because of the persistent tenesmus and discharge of pus, scybala were still present.

Nature of Ulcerative Colitis

It seems therefore that the first group described is the only type which can be reasonably termed ulcerative colitis, for here alone is a generalised primary ulceration of the colon. Is it a specific disease entity ? Recourse must now be had to the histological appearances. For those who look for a sign, for some specific cell change, there will only be disappointment. Surgical removal of the colon has enabled us to see that the over-all picture is one of destruction of epithelium and underlying mucosa followed by attempts at healing from epithelial islands remaining from the bottom of the crypts (fig. 5*a*). The situation is in every way analogous to a burn of the skin, except that in the colon secondary infection *always* supervenes, rendering healing more difficult. A burn heals from the epithelial cells at the bottom of hair follicles and sweat ducts which dig deep into the dermis ; if destruction goes beyond this level, healing will not take place. Thus in the colon some agent destroys mucosa to a variable depth ; even if epithelium is renewed it is often debased in form, no longer columnar, a weak " rice-paper " scar prone to break down at the slightest provocation (fig. 5*b*). Furthermore, the

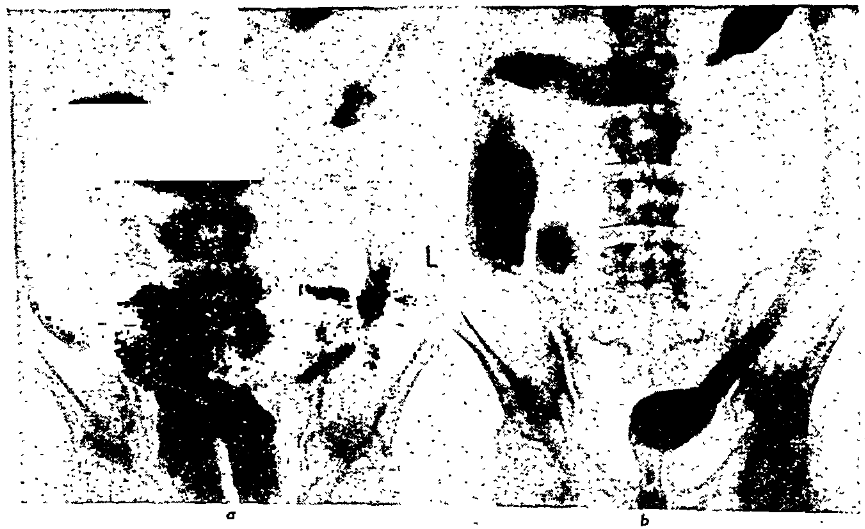

Fig. 3—True "*idiopathic*" ulcerative colitis in case I, showing ileal changes, colitis, and carcinoma in transverse colon : a, after barium meal ; b, after barium enema.

Kuzell et al (1952) report in 4 of their cases severe digestive disturbances during treatment, associated with reactivation of pre existing duodenal ulcers, 1 of these patients had been receiving the drug intramuscularly. Cudkowicz and Jacobs (1953) mention 2 cases in which peptic ulceration was reactivated—in 1 case after fourteen years' quiescence. These 6 cases do not seem to justify including reactivation of peptic ulceration among the toxic effects of phenylbutazone, and the risk of acute ulceration is probably the same with or without previous dyspepsia.

Skin Reactions

These have been fairly common varying from slight petechial rashes to severe maculopapular eruptions. Most cases have, however, been mild and have cleared up with administration of anti-histamine drugs. Rashes are said to be rare at the start of treatment but to develop usually after ten to fourteen days or at the start of a second course.

Granulopenia

Granulopenia has been reported in at least 11 cases (*British Medical Journal* 1952, Crowther and Elgood 1952, Loxton et al 1952, Hinz et al 1953, Jarvis 1952, *Lancet* 1953, Tait 1952).

In the case described by Crowther and Elgood (1952) the patient had been receiving 1200 mg daily by mouth for ten days when she developed a facial rash and slight œdema of the ankles. The dose was reduced to 600 mg daily, but a week later she became jaundiced and pyrexial, and the drug was discontinued. After a further week, during which she continued to be pyrexial, she was found to have an absolute agranulocytosis. In a case reported by Jarvis (1952) severe neutropenia developed after fifteen days' treatment with 1200 mg daily by mouth. Hinz et al (1953) report neutropenia arising after forty-six days' treatment with 400 mg daily by mouth. In a case of agranulocytic bronchopneumonia which terminated fatally (*British Medical Journal* 1952) the patient had received 800 mg daily for a total of four weeks the drug having been given in two fortnightly courses separated by an interval of two weeks.

Discombe (1952) has suggested that agranulocytosis after treatment with other drugs known to be occasionally toxic, such as amidopyrine, may be an allergic manifestation and therefore develop only after initial sensitisation. Israels and Wilkinson (1937) noted that in certain patients who had recovered from amidopyrine agranulocytosis a subsequent dose of the drug caused leucopenia.

Purpura

Purpura has been reported by Stephens et al (1952) and Davies et al (1952). In none of these cases was the condition attributable to a fall in the platelet-count. Stephens noticed thrombocytopenia in 31 of a series of 188 cases, usually this complication appeared only after three to four weeks of treatment, and in none was there purpura.

Jaundice

Jaundice has been reported by Solomon (1953) in 2 cases, but he presents little evidence that phenylbutazone was responsible.

SUMMARY

Complete agranulocytosis developed in a 53-year-old woman during treatment with phenylbutazone. Post mortem the stomach contained many superficial erosions.

I wish to thank Dr W J Hay, consultant physician, for permission to report the case and for help in the inquiry, and Dr A. G Rickards for his advice and criticism.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Phenylbutazone

At its annual general meeting on June 10, with the president, Dr **Donald Wilson**, in the chair, the section of physical medicine discussed Phenylbutazone ('Butazolidin') as a Therapeutic Agent in Arthritis.

Dr **John Shulman** said that phenylbutazone had been used by a number of clinicians for about a year, and some assessment of its value in rheumatic disease should now be made. His first experience of the drug had been in the form of 'Irgapyrin,' which was a mixture of phenylbutazone and amidopyrine, he felt certain that neither drug modified the toxic effects of the other, as had been suggested. Turning to the pharmacological effects of phenylbutazone, he said that there was no doubt that the drug raised the pain threshold; and it was also claimed that it had an anti-inflammatory action and a possibly associated effect on capillary permeability. In gout the blood uric-acid level was reduced. The most important side-actions were fluid and sodium retention and a toxic action on the bone-marrow. Although reduction of urine volume and sodium output were also found with corticosterone, phenylbutazone had no effect either on 17-ketosteroid or potassium output, or on the eosinophil-count, and the urinary effects could perhaps be attributed to increased reabsorption in the tubules. With regard to the toxic effects on the marrow, Dr. Shulman suggested that these could be minimised by confining phenylbutazone treatment in rheumatoid arthritis to active cases, as in gold therapy. He thought it likely that as much of the functional marrow was supplied by blood-vessels of epiphyseal and thus para-articular origin, there was in the active stage of rheumatoid arthritis a barrier to the blood-supply of the marrow which protected it against the harmful effects of toxins and drugs such as gold and phenylbutazone. Among diseases other than rheumatoid arthritis gout and ankylosing spondylitis had shown the best response. From his experiences in the treatment of 500 cases, mostly rheumatoid arthritis he thought phenylbutazone was valuable as maintenance therapy after cortisone or gold. but that it should never be used in the quiescent stage of disease. The maximum maintenance dose should not exceed 400 mg per day—if possible, 200 mg per day. Repeated regular blood-counts were essential to detect incipient agranulocytosis. The future of phenylbutazone therapy probably lay in the management of cases unsuitable for gold or cortisone.

Dr **Rhys Davies** had had eighteen months' experience of phenylbutazone. Initially, 12 patients with rheumatoid arthritis were treated in a pilot experiment, and most of them benefited. showing few toxic effects. Then 16 further cases carefully controlled, had confirmed initial conclusions and were reported elsewhere. He described a third group of 145 patients with rheumatoid arthritis all of whom were under observation before beginning treatment. Phenylbutazone was given by mouth starting with not more than 1 g daily, and reducing to a maintenance dose of not more than 800 mg on alternate days. Other drugs especially barbiturates,

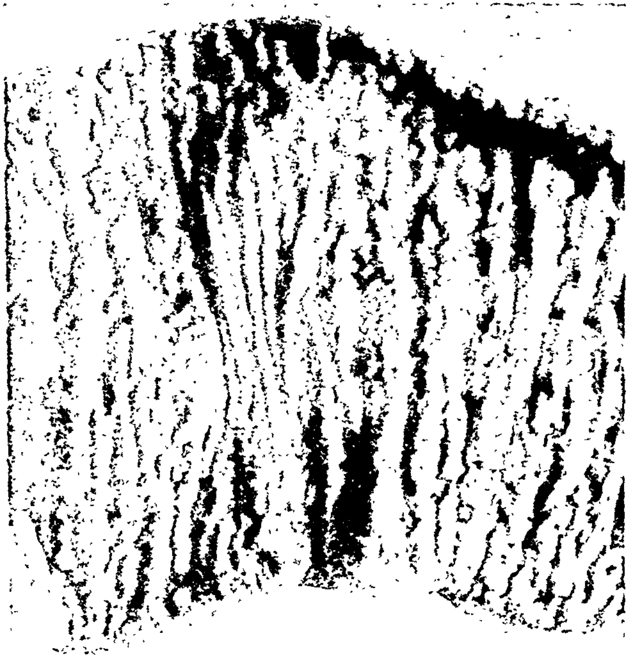

Fig. 4—Mid-ileum from case I. These changes were present from jejunum onwards.

orifices of crypts become blocked, with the result that small intramural abscesses remain buried in the mucosa to start the ulceration anew (fig. 5c).

These facts point in one direction. Ulcerative colitis is essentially recurrent or persistent; *one limited attack of diarrhœa does not constitute the disease: surely*, then, it must be the outcome of an initial blow to the colon of such severity as to leave the mucosa either in a permanently unhealed state or so weakened as to be prone to break down recurrently at the slightest strain, as in chronic ulcers of the leg. Put another way, ulcerative colitis is not a specific disease which hangs about the system to flare up from time to time.

The clinical facts support this. The history, in a definite proportion of cases, starts with a recognised attack of bacillary dysentery, and rarely amœbiasis is to blame; by the time ulcerative colitis has supervened all evidence of bacillary or amœbic infection has passed away. The fact that a clinically normal interval may occur between the definitive infection and the onset of ulcerative colitis does not invalidate the argument, for the bowel can heal, but sometimes imperfectly with the result that its breakdown later under the stress, perhaps, of another disease or a mild non-specific colon infection, is inevitable. The interval may be long.

Case 4.—In 1929 a man, then aged 23, had an attack of dysentery (thought to be bacillary) while resident in Aboukir. In 1948 he developed ulcerative colitis with persistent diarrhœa until he was operated on in 1952. In the interval he had had two mild attacks of diarrhœa lasting no more than 3 days.

Whether an attack of bacillary dysentery is to be followed by ulcerative colitis or not is a matter of the degree of destruction in the first instance. There are, of course, many cases with no past evidence of dysentery; but, since most of them had their first attack of diarrhœa outside hospital, an unnoticed food-poisoning, of the type which recurs so commonly in modern communities, may have started the chain of events. Even the failure to find incriminating organisms in the rather rare acute fulminating attack does not exclude this explanation, for the colon must be subject to chemical and biochemical traumata whose nature we do not at present understand, as recent experiences with chloramphenicol and aureomycin have shown (Reiner et al. 1952); the sensitisation phenomena suggested by Andresen (1940, 1951) may on occasion provide the initial blow. I have never seen ulcerative colitis follow typhoid fever or other members of the enteric group; the rarity of this combination can be explained by the distribution of the original ulceration, which leaves ample mucosa intact for purposes of healing.

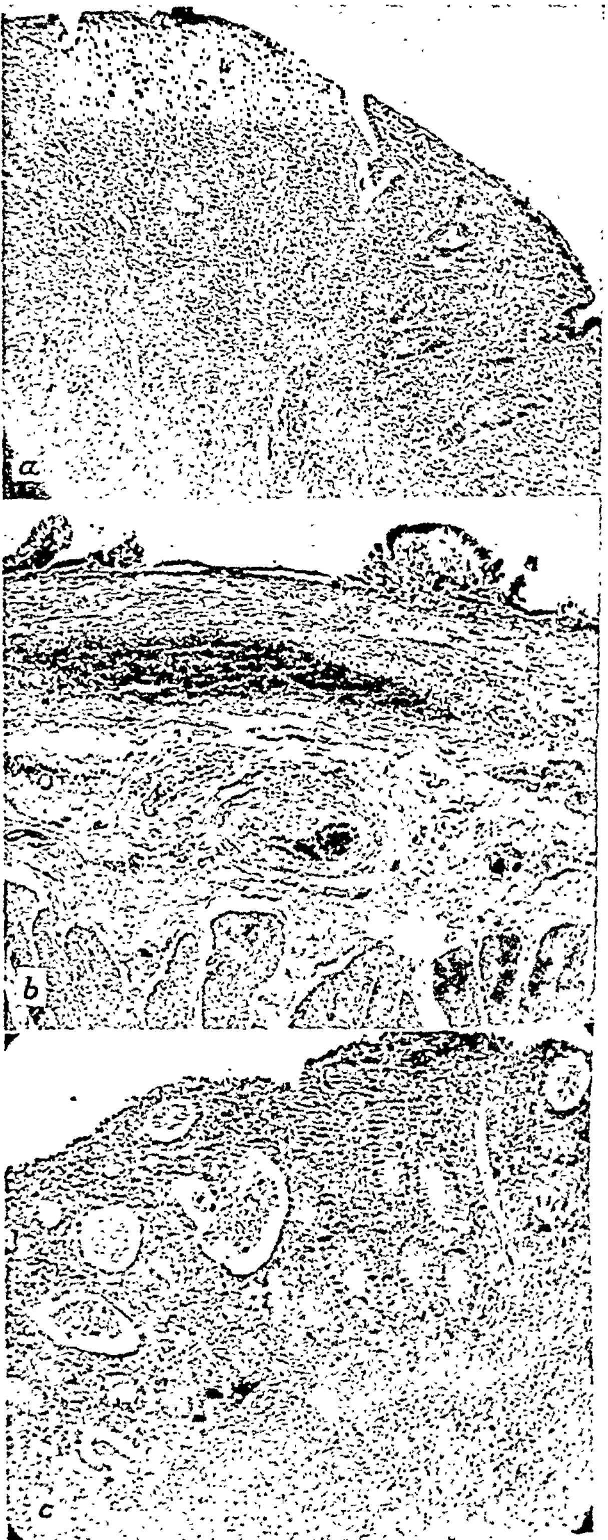

Fig. 5—True "idiopathic" ulcerative colitis: *a*, low and almost *cubical epithelium growing out from crypts and covering inflamed mucosa*; *b*, mucosa lost down to muscularis mucosæ, which is covered with flattened debased epithelium (a small pseudopolyp is *visible*); *c*, unobstructed crypts alongside crypts distended with pus.

which may mask toxic effects, were avoided. When the cases were assessed on a grading basis, there was no evidence of an effect on the rheumatoid process. A third of the patients showed some improvement in function, but the main effects were analgesia (only 10% showed no relief) and euphoria. Dr Davies thought that this euphoria was a very great help in the management and rehabilitation of patients with rheumatoid arthritis. Patients with ankylosing spondylitis, gout, and sometimes osteo-arthritis of the hip often improved when other analgesics had failed. Salt restriction was an important precaution in patients on phenylbutazone, and regular blood counts, especially during the first six weeks of treatment, were essential. Side effects could be allergic (rashes, angioneurotic œdema, asthma) or toxic. 10% of the patients had gastro-intestinal symptoms of more or less severity. Granulocytopenia had occurred in only 1 of his cases. Dr Davies had seen 2 deaths in patients taking phenylbutazone, and he thought that possibly a generalised drug sensitivity was responsible. He urged that phenylbutazone should not be used unless other analgesics had failed. It was to be regarded as a useful ancillary to rest, physical measures, and chrysotherapy.

Dr **Wilson** emphasised the great care needed in using phenylbutazone. He described a patient with renal dystrophy who had died in uræmia three months after starting and a month after finishing a course of the drug. He also believed that the severity of intercurrent infections was increased by phenylbutazone treatment.

During the discussion, Dr G O **Storey** described an elderly man, with typical rheumatoid arthritis treated with phenylbutazone, who died suddenly after admission to hospital with signs of toxicity. There was microscopical evidence at necropsy of a general hypersensitivity response. He emphasised the importance of careful post-mortem examination of patients dying suddenly while under treatment. Dr **Michael Mason** showed two slides illustrating a series of comparisons made between phenylbutazone and corticotrophin therapy in rheumatoid arthritis. Subjective and functional improvement produced by the two drugs appeared similar in his series; the erythrocyte-sedimentation rate, which fell during corticotrophin treatment, was unaffected by phenylbutazone. Dr J B **Jessiman** had observed toxic effects in 20 out of 22 patients with rheumatoid arthritis treated with phenylbutazone. All these cases had had previous treatment with gold or copper, to which they were sensitive. Dr N S **Craig** pointed out that aplastic anæmia may supervene very suddenly, and that regular white counts were no insurance against this. He thought that phenylbutazone was a highly dangerous drug. Dr C J S **O'Malley**, speaking of his experience in a rehabilitation centre, said that phenylbutazone enabled patients to undergo the rehabilitation course who, without the drug, would have been unable to attempt it. Dr **Cedric Hirson** said that Dr Craig's view of phenylbutazone, had it been applied to the sulphonamides when they were first introduced, as some people had advocated, would have led to their abandonment. Other speakers commented on the lack of unanimity in the dosage schemes used.

In reply to some of the points raised, Dr **Rhys Davies** said that in his experience sudden death attributable to the drug was due to acute pulmonary œdema, probably a manifestation of generalised drug hypersensitivity. With regard to blood-uric-acid levels in acute gout he had observed levels to fall from 7–10 mg. to less than 4 mg. within three days of starting phenylbutazone. He pointed out that the drug was detectable in the blood for forty-eight hours after a single dose, and that therefore maintenance doses every two days should be adequate. Dr **Shulman**, while recognising the occurrence of unheralded aplastic anæmia and agranulocytosis, thought that in most cases it could be anticipated by routine white-cell and platelet counts.

AMERICAN RHEUMATISM ASSOCIATION

In his presidential address at the annual meeting held in New York on May 28-29, Dr C **McEwen** (New York) said that in its twenty-two years the association had seen great advances in the scientific quality of the papers presented, and now counted 800 members. Yet this advance was slow when compared with advances in other fields of medicine. There was still only one member of the association for every 12,000 victims of the rheumatic diseases, and only four or five of the major universities in the United States had an established arthritis department supporting full-time faculty members interested primarily in the problems of these diseases. It was time to seek from the Federal government, via the Public Health Service, support for further such departments. Only in this way could the study of the rheumatic diseases attract more workers and advance more rapidly.

Rheumatic Diseases

S **Cobb**, F **Anderson**, and W **Bauer** (Boston) reported a life-table study of 583 patients admitted to hospital at some time with rheumatoid arthritis, and followed for an average of 9.6 years. There had been 137 deaths, which on analysis showed that while the development of this disease did not influence the longevity of patients over 50, under that age expectation of life was considerably reduced: such patients succumbed to valvular heart disease, to infections of all sorts, or to pulmonary embolism, with a much greater frequency than others of the same age group.

WORK IN PROGRESS

E **Gardner** (Detroit) reviewed the blood and nerve supply of articular structures.

The synovial membrane was, he said, a highly vascular structure, which showed, besides an abundant capillary network, a type of thick-walled arteriole associated with arteriovenous anastomoses, and probably concerned with the regulation of local blood flow and temperature. He analysed the various types of nerve ending found in the joint, and showed that stimulation of some of these could produce visceral reflexes (i.e. hypotension) as well as local reflexes. J H **Kellgren** (Manchester), reporting studies of incorporation of labelled glycine into the tissues of rats, noted that adult collagen, once formed, showed little if any metabolic activity. However there were more soluble forms of collagen which did show a change. Formed collagen could not be regarded as necessarily inert. There was evidence that in rheumatoid tissues the normal collagen was replaced by an amorphous fibrinoid material—possibly a glyco-protein. These changes had been followed by electron microscopy, by X-ray diffraction, and by chemical analysis. K **Meyer** (New York) reported work on hyaluronidase preparations. Those of animal origin differed from those of bacterial origin. Of particular interest was the fact that bacterial enzymes not only split the hyaluronic acid chain molecule, but also modified the end grouping of the hexuronic acid component. This might have antigenic significance. **James Rhinehart** (San Francisco) had treated tissues with hyaluronidase, and had stained them before and after with a colloidal iron stain specific for sulphated polysaccharides. He showed that the mucoid polysaccharide-containing, interfibrillary substance of connective tissue seemed to be the site of the earliest lesion of rheumatic fever. This material swelled and became infiltrated with fibrin and possibly other components of the blood.

L **Sokoloff** (New York) had studied very early nodules of rheumatoid arthritis and had found that such lesions were highly vascular. This contrasted with the necrotic, avascular, and fibrous mature nodule. Necrosis, when it occurred, did so in relation to the blood vessels in such a way as to suggest that some

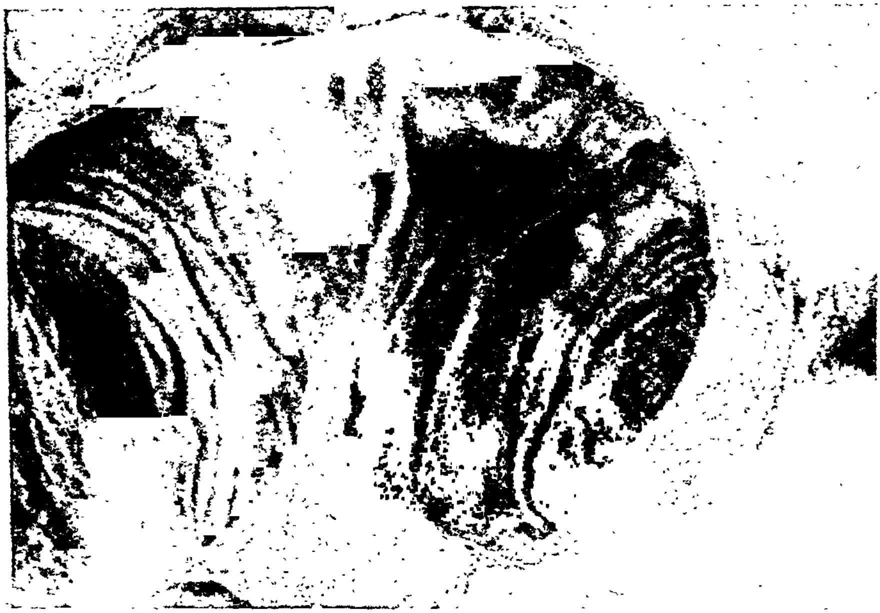

Fig. 6—Normal ileocæcal valve, showing crescentic fold.

There remain two questions regarding the significance of the pseudopolyps and the site of greatest destruction. The pseudopolyps have no significance in relation to the origin of ulcerative colitis; they are evidence only of bowel damage, being more often islands of mucosa remaining in a sea of destruction, less often granulomata covered with debased epithelium. It seems likely that there is a physiological reason why the left colon bears the brunt of the inflammation; the fact that the damage is greatest here cannot be taken as evidence that the disease starts at this site, but only that the weakened mucosa is broken down more readily and more completely here.

The Ileum in Ulcerative Colitis

As indicated above, it remains to explain why the ileum is sometimes involved in ulcerative colitis. Crohn (1949) rightly described it as due to a backwash of infected material from the colon, though he placed "right-sided colitis" with its associated ileitis in the same group and thereby inflated the incidence to 24%. In a personal series of 55 patients operated on I have seen ileitis only 3 times: during the same period 9 additional cases of ileocolitis were observed. This complication of ulcerative colitis is entirely due to the destruction of the ileocæcal valve. If the large bowel, removed at operation, is first distended to its natural size with fixative before being cut open for examination, the many mucosal folds, caused by contraction following fixation in the more usual way, are smoothed out and the bowel lumen can be studied in its natural form. (I am indebted to Dr. Cuthbert Dukes for drawing my attention to this method.) In normal bowel it will be seen that the cæcum is separated from the ascending colon by a crescentic fold, which is quite constant and passes about three-quarters of the way round the bowel lumen (fig. 6). On the cæcal side of this fold lies the ileocæcal valve, a horizontal slit, its upper lip formed by the fold which overhangs the lower lip in such a way that the orifice is directed towards the cæcum and away from the fæcal column contained in the colon. As the lips have a depth of ¼–½ in., the mechanism is similar to that of the mitral valve. It is quite competent, as handling of the cæcum and colon at laparotomy will reveal, when neither air nor fluid can be expressed into the ileum. The fact that barium can flow into the ileum from a barium enema in normal people does not argue that the valve is physiologically incompetent, for these are abnormal circumstances. The weight of barium, together with the head of pressure behind it, causes the cæcum to sag; this pulls down the medial wall together with the lower lip of the valve; the orifice opens and barium spills through into the ileum.

blood-borne necrotising agent seeped out of the vessels into the tissues around, finally affecting the wall of the vessels itself, which then became obstructed by thrombosis J P KULKA (Boston) confirmed this work and had shown, by serial section, that many of the vessels involved in such early lesions were venules In lesions only one or two days old there was an œdema of the ground substance of the tissues near such a vessel, and then infiltration of it with a fibrin-like material apparently exuding from the vessel W D ROBINSON (Ann Arbor) described 4 cases of rheumatoid arthritis which developed diffuse or localised arteritis The lesions of the vessel walls differed from those of polyarteritis nodosa, and resembled rheumatoid granulomata elsewhere Clinically these patients had shown peripheral neuritis and/or lesions due to coronary or cerebral occlusion M A OGRYZLO (Toronto) drew attention to those cases of classical rheumatoid arthritis with nodules, which developed a fulminating involvement of other viscera manifested by fever, weight loss, nodule formation, cardiac and pulmonary disorder renal changes, and severe myositis In some the lupus erythematosus cell phenomenon was present, but, as several speakers pointed out, this could no longer be considered diagnostic of this disease

T B BAYLES (Boston) reported some of the many ways in which scleroderma may affect viscera as well as the skin Of his 15 patients, 14 had cardiac involvement Bronchiectasis, breast changes, ulceration and stricture of the intestinal tract, and myositis were not uncommon

The differential sheep cell agglutination titre was discussed by A S JACOBSON (New York) Using Heller's modification, he had found it to be positive in 74% of cases of active peripheral rheumatoid arthritis A positive test was found most often in cases with nodules and was more frequent in the male sex There were 2 6% of false positives, and most of these were in cases of other "collagen" disease In the subsequent discussion other workers reported attempts at characterising the factor responsible It seemed probable that it was a macromolecule, of molecular weight 15,000, stable between pH 3 and pH 11 and in the presence of 30% alcohol It reacted unlike a protein, although it seemed to be associated with the γ globulin fraction of the plasma-proteins

SURGICAL MEASURES

R L PRESTON (New York) described his method of reconstruction of the knee-joint in rheumatoid arthritis In the more severe cases he used both anterior and posterior arthrotomy, followed by synovectomy and removal of intra-articular deformities and adhesions The tibial tubercle was moved distally to restore function to the stretched quadriceps Corticotrophin (A C T H), 100 mg daily, was given for one week before and two weeks after operation to reduce pain and scarring Exercises maintained muscle strength and joint range Before operation all 18 of his patients were disabled by flexion deformity In 16 the operation was satisfactory, and 11 who had been followed more than six months had maintained good function

M C COBEY (Washington, D C) had experimented with combining plastics with other materials for splints Finally he had evolved a mixture of plaster of-paris and 'Melmac' resin, combined in such a way that plaster bandages would be impregnated with both simultaneously, so that wetting was followed by setting of both the plaster and resin The resulting splint was more resilient, lighter, and cheaper than plaster alone As it was four times as strong as plaster, less material was required Two 4-inch plaster bandages would make a satisfactory leg cast which with a little reinforcement could be used for weight bearing Such casts were porous but unaffected by moisture or urine, and were often in satisfactory use continuously for a year

MEDICAL TREATMENT

From the Mayo Clinic L E WARD (Rochester) reported a study of cortisone and hydrocortisone, and their esters in rheumatoid arthritis Although weight for weight the various steroids differed in their antirheumatic potency, the more powerful the preparation the more likely it was to produce undesirable toxic effects

J H KELLGREN (Manchester) and A BRADFORD HILL (London) described the early results of a small but strictly controlled Medical Research Council therapeutic trial of cortisone and aspirin, as suppressive agents in rheumatoid arthritis Selecting only early cases, before permanent deformity had occurred, and judging the results by the ability of their patients to return to work or normal daily activity, they found no differences between the two treatments It was as yet too early to assess results in the prevention of permanent deformities

Members of a committee of the American Rheumatism Association, who also were concerned with assessment of the benefits of cortisone in rheumatoid arthritis, reported a preliminary inquiry into the ways in which the clinicians were already using cortisone for this disease This was not a controlled study, so the results could not be used for the comparison of cortisone against other treatments Nevertheless it showed that there were in practice a surprising number of limitations to the use of this preparation They hoped to use the information thus collected in setting up a large scale controlled study covering both early and late cases

Three papers reported on the use of cortisone in rheumatic carditis MAY G WILSON (New York) treated carditis in 33 patients, using an average of 150 mg of corticotrophin or 300 mg of cortisone daily for about seven days She thought that carditis could be terminated in this way, and her patients became ambulatory in two to three weeks In her long experience of rheumatic fever covering many thousand patients over twenty years, she had not seen so effective a remedy as cortisone On the other hand ANN G KUTTNER and JANET S BALDWIN (New York) had treated 7 patients, fourteen days or less from the onset of their first rheumatic attack, with cortisone or hydrocortisone for from twenty one to sixty three days, and had found that 5 of these patients (after follow-up periods up to two years) had established valvular damage, in 1 other the rheumatic progress was still active LAWRENCE GREENMAN (Pittsburg) had treated 49 children in their first attack of rheumatic carditis with cortisone in a dosage of 300 mg per day for six weeks, decreasing to zero during the next two weeks He found, on follow up, that 9 out of 10 patients whose duration of disease was less than fourteen days before treatment, recovered with normal hearts The results were less good in those cases whose carditis had been active for longer than fourteen days B F MASSELL (Boston) agreed that massive suppressive dosage continued for several months was effective in preventing permanent cardiac damage EDWARD E FISCHELL (New York), discussing these results, noted the great variability of the clinical course of rheumatic fever Although the results were encouraging they were from uncontrolled studies and this fact should be remembered in assessing their significance and the discrepancies between them

W C KUZELL (San Francisco) had treated 800 patients suffering from a variety of rheumatic diseases with phenylbutazone ('Butazolidin') and had found it an effective and useful, though temporary, suppressive agent Patients with gout and ankylosing spondylitis showed the best responses Toxic effects had been fairly common, occurring in 381 out of the 800 patients and in sufficient severity to cause discontinuation of therapy

When ulceration has persisted in the cæcum for some time, the crescentic fold is destroyed, the lips of the valve are then lost, and the cæcal wall is directly continuous with that of the colon. At this stage the ileocæcal junction appears as a circular porthole constantly open. The ileum beyond then develops a granular mucosa and a thickened wall (fig. 7). That this ileitis is of no more than secondary significance is shown by the fact that ileostomy can be performed in such cases above the site of gross change without subsequent inflammation developing above the stoma, provided, of course, the stoma is efficient. Ileostomy dysfunction (Warren and McKitterick 1951), from stenosis of the stoma and partial obstruction, will induce an inflammation in the ileum which has nothing to do with the original disease, as will the simple trauma of an indwelling tube. A significant point in the ætiology of ulcerative colitis is the fact that the bowel does not become affected with the original disease above an ileal stoma; if ileitis does develop, it is due to one of the factors just mentioned or because the case is an unrecognised ileocolitis.

Crohn's Disease and Ulcerative Colitis

A study of ulcerative colitis cannot be complete without considering Crohn's disease. It is true that when Crohn's disease attacks the colon primarily it can be widespread and far more so than is generally recognised from the study of the gross lesion, which is usually circumscribed. If a colon, attacked by this disease, is prepared in the manner described by Dr. Dukes, lesions can sometimes be observed beyond the area of gross damage. In the specimen shown in fig. 8 the ascending colon was grossly disorganised; yet the *external* appearances of the bowel beyond the hepatic flexure were perfectly normal, with no thickening. However, scattered rather sparsely throughout down to the sigmoid, shallow "aphthoid" ulcers about $^{1}/_{8}$–$^{1}/_{4}$ in. in diameter were visible, while here and there scars, resembling those seen in an atheromatous aorta, indicated an area which had healed. It would be impossible to detect these changes on external observation of the bowel at laparotomy, and their unsuspected presence may explain the high recurrence-rate following resection in this disease.

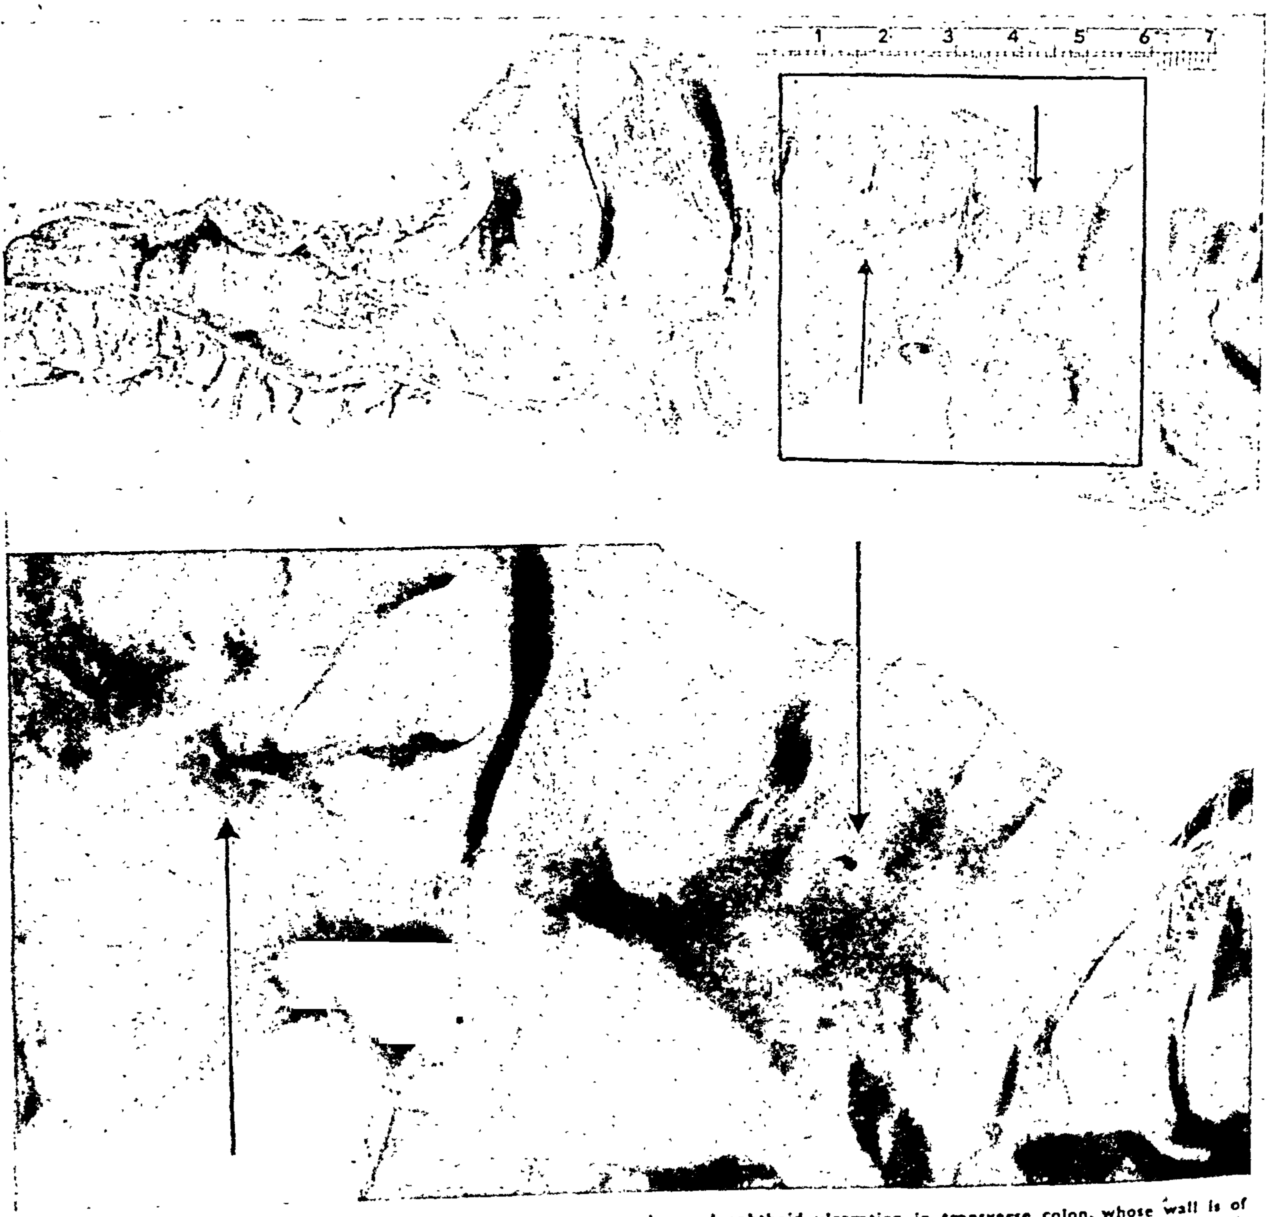

Fig. 8—Crohn's disease of cæcum and ascending colon: above, scarring and aphthoid ulceration in transverse colon, whose wall is of normal thickness; below, enlargement of inset. Arrows point to scarring on the left and an "aphthoid" ulcer on the right. Scale in inches.

in about 15% **Elmer E Yeoman** (Tucson) had treated 40 patients suffering from rheumatoid spondylitis with this drug for periods up to two years In his series the drug had been discontinued in only 1 because of toxic effects 11 patients had gone back to work and 3 became fit enough for surgery He emphasised that the maintenance dose should not be above 200 mg per day **Ephraim P Engleman** (San Francisco), on the other hand, found the toxic effects of this drug to be both serious and frequent Jaundice occurred in 4 patients, of whom 1 died 4 patients showed heart-failure 1 of these died, and at necropsy there was a diffuse arteritis involving most of the viscera, including the heart 2 patients developed optic neuritis, 1 becoming permanently blind 2 had granulocytopenia, with 1 death Other toxic reactions included peptic ulceration, psychosis, and purpura His patients had received the drug for from two to twenty-eight days at a dose level of between 300 and 800 mg daily

DeWitt Stettin (New York) reviewed recent work employing tracer substances bearing on the metabolic defect in gout In normal men there was a miscible pool of uric acid of about 1 1 g which was replaced each day to the extent of 75% by newly formed uric acid About 80% of the uric acid disposed of each day appeared in the urine as uric acid The remainder was broken down into urea and ammonia In the gouty subject the miscible pool of uric acid might increase to 30 g This was greater than the amount that could exist as a saturated solution in the total body-water, and it appeared certain that uric acid tophi could contribute to the pool by continuous resolution and precipitation Uricosuric drugs such as 'Benemid' could shrink this miscible uric acid pool in gout In some, but not all, gouty patients there was an increased rate of synthesis of uric acid from dietary glycine

Reviews of Books

Ciba Foundation Colloquia on Endocrinology

Vol 5 *Bioassay of anterior pituitary and adrenocortical hormones* Editor G E W Wolstenholme, O B E, M A, M B, assisted by Margaret P Cameron, M A, A B L S London J & A Churchill 1953 Pp 228 25s

The bulk of this book consists of the texts of individual papers presented at the colloquium Most of these papers describe one or more methods of assay of each of the anterior pituitary hormones or of the adrenal corticoids Although most of the papers are complete, self-contained, and descriptive accounts, the book as a whole suffers from the lack of a critical appraisal of the merits of the different methods, and the reader may find it difficult to make his own assessment Moreover, as the chairman pointed out in his summing-up, the different purposes for which bioassay is required—namely, the control of manufacture, fundamental research, and the clinical diagnosis of hormonal dysfunction—make different demands on the design of the assays, thus, clinical diagnosis demands an assay method of high sensitivity, but not necessarily of great precision, while control of manufacture requires precision but not necessarily sensitivity There is no clear indication of the part that the assays described can play in these very different fields The fault does not lie with the authors nor with the editors it results from the written reproduction of the spoken word, which cannot recapture the inflexion of voice, the subtle emphasis, or the flat uninterestedness that provided a constant critical commentary at the meeting itself And if this is true of the papers themselves, it applies even more to the verbatim reports of the discussion which, on the whole, make colourless reading

Nevertheless in this single volume are to be found up-to date accounts of bioassays of all the anterior pituitary hormones and of the adrenal corticoids, and the collection of these methods from the literature would otherwise be a formidable task The book is likely therefore, to be of considerable value to endocrinologists in both the clinical and the research fields It is arranged in six parts, covering general principles, thyrotrophic hormone, gonadotrophins and prolactin, growth hormone corticotrophin, and the adrenocortical hormones respectively It is well turned out, with admirably clear tables and figures, and the latter, including some line drawings of a bioassayist at work, should have a wide appeal

The Œsophagus and its Diseases

Eddy D Palmer, M D, F A C P, lieut colonel, Medical Corps, U S Army, chief, gastro intestinal section, Walter Reed Army Hospital London Cassell 1953 Pp 553 93s

The foreword of this book states that "the œsophagus is coming into its own from a sort of 'No Man's Land'" and the author supports this contention by discussing the many and diverse disorders to which the œsophagus is heir He correlates and analyses various views advanced in recent years, but is perhaps too reticent about his own opinions

The opening chapters survey œsophageal anatomy and physiology, and illustrate the difficulties of studying any abnormality of deglutition Congenital abnormalities are well handled, but the section on diaphragmatic hernias, particularly the hiatus type, is not satisfactory, and the work of Allison and Johnstone is not mentioned in this connection The ætiological factors in achalasia and cardio spasm are fully discussed, but the reader will find it hard to decide which form of treatment, if any, is recommended A number of operations for cardiospasm are described which must inevitably lead to the undesirable reflux of gastric contents into the œsophagus (Accepted teaching in this country favours the Heller type of operation) Some of the most interesting and informative chapters are concerned with more unusual disorders, such as benign tumours, scleroderma, and varices

No attempt is made to go into operative and technical details, which would have made the book too long It is well produced and adequately illustrated, and will be valuable for reference

Histochemistry

Theoretical and Applied A G Everson Pearse, M A, M D, D C P, lecturer in histochemistry, Postgraduate Medical School of London London J & A Churchill 1953 Pp 530 60s

The author follows Prof J R Baker in acclaiming Francois Vincent Raspail (1794–1878) as the founder of histochemistry The science received a temporary set back after the introduction into histology of aniline dyes by Beneke in 1862, but it revived with the publication in 1936 of Lison's *Histochimie Animale* Since then its growth has been rapid—so rapid, in fact, that it has been hard for the histologist and histopathologist to keep level with developments There are many, therefore, who will be grateful to Dr Pearse for amassing so much information and treating it so ably and critically The work includes a useful chapter which deals briefly with the various physical methods which can help the modern microscopist There are many helpful illustrations, while technical methods are conveniently contained in a series of appendices which correspond to the various chapters This book will be of value to all concerned in the preparation and interpretation of tissues for microscopy

---

Medicine (Vol 1 *The Patient and His Disease* 2nd ed Edinburgh E & S Livingstone 1953 Pp 410 25s) — Never have so many textbooks of medicine appeared in such a short time as in this post war period We welcome this second edition with its implication that the first edition is sold out Among the few that are good, Dr A L Clark Kennedy's ranks high mainly because it is not a catalogue of *facts, nor yet an omnibus of authors* nor even a practical guide but a straightforward account of how the problems of health and disease appear to a thoughtful and gifted physician Knowledge and experience seasoned with sincerity, humility and humanity are the ingredients A book to be read with profit by all from the senior physician to the junior clerk

SUSPECTED VIRUS INFECTIONS OF RESPIRATORY TRACT AND CENTRAL NERVOUS SYSTEM

DIAGNOSIS BY SEROLOGICAL METHODS

REPORT BY THE VIRUS REFERENCE LABORATORY,* PUBLIC HEALTH LABORATORY SERVICE, COLINDALE, LONDON

THE Virus Reference Laboratory, Colindale, began to make certain serological tests for the diagnosis of suspected virus infections of the respiratory tract and central nervous system in 1947–48. New tests were added as conditions permitted; and by 1949 cases of suspected virus infection of the respiratory tract were being investigated for antibodies to influenza viruses A and B, the psittacosis-lymphogranuloma-venereum (L.G.V.) group of viruses, *Rickettsia burneti*, and *Streptococcus M.G.*, and cases of suspected virus infection of the central nervous system for antibodies to the viruses of lymphocytic choriomeningitis (L.C.M.) and of mumps and to leptospires. In the ensuing two years a considerable number of serological tests were made on, and some viruses were isolated from, material from patients, mainly in hospitals, from all parts of England and Wales and to a small extent from Scotland; most of the specimens have, however, come from London and the Home Counties. A number of the positive results have already been recorded in papers by different physicians on series of patients (Crofton et al. 1951, Jennings 1952) or interesting individual cases such as Q fever, psittacosis, mumps-meningoencephalitis without parotitis, and lymphocytic choriomeningitis; and brief remarks on part of the respiratory-tract and neurological series have been reported from the laboratory (Marmion 1951, MacCallum 1950).

Although the Virus Reference Laboratory has coöperated with many hospitals and physicians and provided pamphlets on instructions for the collection of specimens and for the interpretation of results of the various tests, many doctors are probably still unfamiliar with the types of test that can be usefully made and are now available for the diagnosis of certain virus diseases. Since the complement-fixation tests for influenza A and B viruses, the psittacosis-L.G.V. group of viruses, and *R. burneti*, and the agglutination tests for *Strep. M.G.* are being made at public-health laboratories at Cambridge, Cardiff, Hull, Manchester, Newcastle, Northampton, Nottingham, and Winchester, and agglutination tests for leptospires at Birmingham, Bradford, Cambridge, Cardiff, Exeter, and Portsmouth, in addition to the Central Health Laboratory at Colindale, and by Dr. J. C. Broom, of the Wellcome Laboratories of Tropical Medicine, London, it seems an opportune time to report briefly the results of tests made in 1949–51, so as to show the relative incidence of causal organisms in suspected virus infections in Great Britain and to indicate whether certain tests are likely to be of help or not in diagnosis. Similar reports are available from various centres in the United States of America (Milzer 1950, Sigel 1950, Smadel 1950).

Information about what specimens are required for the investigation of suspected virus diseases, and the manner of their collection and transport to the laboratory, is given in recent textbooks—e.g., Bedson et al. (1950) and MacCallum (1951)—and papers and is not dealt with here. Serological diagnosis is, of necessity, the routine method of diagnosis in virus diseases. The isolation of viruses necessitates the use of fertile hens' eggs or animals such as mice, guineapigs, rabbits, hamsters, ferrets, and monkeys, making it a more expensive and formidable task than the isolation of bacteria. In addition, most of the laboratory animals carry latent viruses; therefore any virus isolated must be tested against the patient's acute and convalescent serum to confirm its origin. In addition, not only may there be human carriers of viruses, but also there can be dual infections—e.g., influenza and Q fever, poliomyelitis and Coxsackie viruses, and poliomyelitis and hepatitis. The examination of a pair of sera collected in the acute stage (ideally before the fifth day of the disease) and the convalescent stage (about the twenty-first day), with the demonstration of a rising titre of antibodies in the second specimen, is essential for an accurate diagnosis. The examination of the serum in the acute stage is necessary since the titre of antibodies may rise to a peak very early in the illness; and the demonstration of an increased titre in the serum in the convalescent stage is essential since antibodies may persist from nine months to two years in different infections.

RESPIRATORY TRACT

We originally intended to concentrate our attention on cases of suspected virus influenza and of primary atypical pneumonia (virus pneumonia). Table I shows that many specimens were also received from patients with a clinical diagnosis of lobar pneumonia or of bronchopneumonia. Influenza B was epidemic from January to the end of April, 1950, and influenza A was epidemic from December, 1950, to the end of April, 1951. The results from sera from patients in outbreaks of influenza in institutions or schools were not included in the table. The term "psittacosis" covers viruses of the psittacosis-ornithosis group. Of the 35 patients considered positive among the 1660 analysed, only 1 had any known contact with a parrot and only 1 with budgerigars; in neither was there a history of concomitant illness. The cases were, on the whole, considered to be examples of ornithosis resulting from contact with pigeons or other domestic birds carrying viruses of this group. The Q-fever figures are slightly greater than might be expected, because the disease was discovered in Kent and Devon at the beginning of the period under discussion, and an intensive search was made.

Of the total number of patients from whom samples were examined in the period from July, 1949, to June, 1951, about a third were rejected from the analysis because the clinical details were either inadequate or described conditions unlikely to be due to a virus infection, or because the sera were taken too early for antibody to be present and no further specimen was sent. Of the remainder (1660), which have been analysed, 44% had only a single sample of serum taken during convalescence and 23% had two or more specimens of serum taken during convalescence. In only 33% of patients were two or more specimens of serum collected of which one was obtained earlier than the tenth day of the illness and a subsequent one from fifteen to thirty days after the onset. It is realised that in some patients the onset may be mild and they do not present themselves until a stage when antibodies are already present; but the idea of infection by a virus or by a rickettsia often appeared to have been an afterthought.

Table I presents the results in the 33% of patients from whom adequately timed sera were collected. (The results in the 23% of patients who had two or more specimens of serum taken during convalescence were of the same order.) It can be seen that about 30% of the patients had antibodies to one or other of the antigens. Of the patients diagnosed as having virus or atypical pneumonia, about 34% reacted to one of the five reagents. The remainder may have been caused by some other unidentified sensitivity developed after only twenty-four hours' treatment The ointment was not tolerated by acute or oozing lesions, possibly because of the nature of the vehicle

---

* Those participating in this work during all or part of the period were Dr. F. O. MacCallum (director), Dr. B. P. Marmion, Dr. A. D. Macrae, Dr. B. Andrews, Dr. A. P. Goffe, J. A. L. McDonald, A.I.M.L.T., and P. Phipps, A.I.M.L.T. The tests for leptospirosis were made by Dr. J. C. Broom, of the Wellcome Laboratories of Tropical Medicine, and for mumps by Dr. C. L. Greenbury, of Stoke Mandeville Hospital.

Topical applications are unexpectedly difficult to assess, for no two skin conditions are identical and all are subject to changes independent of treatment Moreover, symptoms cannot be measured objectively, and they can be influenced by the enthusiasm of the doctor armed with any new preparation Treating a symmetrical eruption on one side only might seem to be the answer, but it has been found in various skin diseases that the untreated side may respond as well as the treated The effect of the vehicle must be considered for example, Reiss and Kern,[16] when testing an anti-histamine ointment, found that over 28% of their patients were relieved of itching by the base alone In these investigations the main control has been the patients' experience with previous preparations, which may have had quite dissimilar bases The reports are therefore open to criticism, but they can at least be taken as an indication that the substance is useful and safe It seems unwise to use it combined in an ointment with an anti-histamine (as is the case in 'Teevex'), for antihistamines can also cause sensitisation dermatitis after repeated local applications On the other hand, it would be helpful to have the pure substance available for incorporation in different media

CHOROIDEREMIA

PROGRESSIVE degenerative lesions of the retina that have been grouped as "abiotrophies" include the different kinds of retinitis pigmentosa, gyrate atrophy of the retina, choroideremia, and several types of macular dystrophy In choroideremia the earliest symptom is night-blindness, then peripheral vision is gradually lost and finally central vision, so that the patient is blind In advanced cases ophthalmoscopic examination shows that the choroidal vessels have disappeared and there is extensive retinal atrophy, affecting the central area least At necropsy the choroidal vessels are either sclerosed or absent, and the outer layer of the retina is extremely degenerate Earlier workers thought that this condition might be a variant of retinitis pigmentosa, with which it shares several features—the strong genetic determination, the progressive nature of the lesion, and in some instances pigmentation of the retina Furthermore some of the female relations of patients with choroideremia were thought to have retinitis pigmentosa

A few years ago American workers[17] described a family of some 600 of whom 33 had choroideremia Sorsby and his colleagues[18] have now given an account of three further affected families These studies show clearly that the condition is distinct from retinitis pigmentosa, which did not occur in these families They also show that the condition is progressive, and in different members of the family at different ages all stages can be seen from symptomless pepper-and-salt changes in the periphery of the retina to the unmasking, sclerosis, and finally disappearance of the retinal vessels Professor Sorsby found advanced choroideremia in a boy aged only $4^{1}/_{2}$, and one man was blind at 25, but blindness is rare before the age of 40, central vision being well retained while peripheral vision is gradually lost

Only males have symptoms of choroideremia, but many of the females in these families had retinal changes typical of the earliest stages of the disease in males There is thus no doubt that the condition is due to a sex-linked gene which is intermediate between a dominant and a recessive, it produces a severe lesion in the male, but in the heterozygous "carrier" state m female it produces only a mild and apparentl progressive disturbance Sorsby and his colleagues that the exceptions to this mode of inheritance de in earlier reports are due to errors in diagnosis, and the carrier state in the female relations of men choroideremia was mistaken for retinitis pigmento

With any genetically determined disorder the ab to recognise the carrier state is most helpful in adv parents on the chance that their children will be affec The sisters of men with choroideremia have an e chance of being normal or of being carriers It important to them to know which they are, since the sons of carriers on the average will go blind Th with normal retinæ can be reassured that there i risk that their sons and grandsons will be affected.

NEW YEAR HONOURS

IN the select company of the members of the Order Merit the place left vacant by the death of Sir Char Sherrington is filled by the appointment of a surge Prof Wilder Penfield, F R S, of the Montreal Neur logical Institute A leader in neurosurgery, he has de classical work on cerebral localisation and the relat problems of epilepsy, and the profession in this country as in Canada, will welcome his new distinction Of th doctors to be created knights bachelor, three a Australians—Mr N M Gregg, the Sydney ophthalm surgeon who first drew attention to the relation congenital cataract to maternal rubella, Dr E Britte Jones, of Adelaide, who has been vice-president of th Royal Australasian College of Physicians and presider of the Medical Board of South Australia, and Dr Pet MacCallum, professor of pathology at Melbourne fo 26 years and chairman of the Australian Nation Research Council and of the Australian National Re Cross Nearer home it is a pleasure to see a knighthoo conferred on Mr Zachary Cope, of St Mary's Hospital who has so well earned this honour as a teacher, as former vice-president of the Royal College of Surgeons as chairman of the Cope Committees—and simply a Zachary Cope Another welcome name is that of Prof Arthur Ellis, once of Toronto but afterwards of th London Hospital and the regius chair at Oxford, whos uncommon sense—whether directed to the kidney or th curriculum—has done so much, in quiet ways, fo medicine and its students We are happy to note that Dr Pridie's notable and far-flung work as chief medic officer of the Colonial Office since 1948 has been reco nised by promotion in the Order of St Michael an St George, and that the distinguished medical head of the Navy and Army, Admiral MacKenzie and Gener Harris receive knighthoods in the Order of the Brit Empire Many other familiar and respected names wi be found in the list we publish on p 87, and to thes we would add that of Mr A Landsborough Thomson D SC, now knighted, whose long service as second secretary of the Medical Research Council makes almost able to claim him as a member of our profession

VACANCIES

READERS who reached the concluding pages of ou last issue will have noticed the analysis of vacan appointments which was printed so conspicuously then As we explained in an annotation, this analysis is to serve as a key, and will be published weekly But now that we have prominently drawn attention to its existence, we are transferring it to our advertisement columns, where it will be found this week on p 30

Dr G F ABERCROMBIE has been elected chairma of the foundation council of the College of Gen Practitioners

THE LANCET

LONDON: SATURDAY, JUNE 20, 1953

Bread

When submarine warfare caused a critical food shortage in 1917 the amount of food available to our human population was increased by milling wheat to a higher percentage—first to 80% and then to 90%. The Food (War) Committee of the Royal Society investigated the "higher extraction" bread, and noted its nutritive superiority: even at a time when the importance of vitamins was but dimly appreciated, the scientific advisers of the Government told the public that "the part of the grain which was formerly rejected contains valuable flesh-forming material and salts." Within a fortnight of the Armistice, however, the Government announced a reduction in the extraction-rate of flour, which would release approximately 18,000 tons of "wheat offal" weekly for farmers, pig-keepers, and others to feed their animal stock. We deplored in 1918 this post-war reversion to whiter bread,[1] and we deplore it again today. Admittedly the changes now proposed will be popular with the uninformed public, and they include compensating safeguards for health. But it is hard to believe that in framing them it is health that has been the first consideration.

During the second world war the history of bread repeated itself with variations. A new and fundamental departure was made when in 1940 the Government announced[2] that, because the 73%-extraction flour at that time in use was lacking in vitamin content, it had been decided to fortify it with vitamin B_1. In making the announcement Mr. (now Sir Robert) Boothby said that this new policy of "fortifying" bread, which had been adopted after receiving a report from the Scientific Food Committee, would be "hailed by scientists everywhere as a great advance"; but in fact it was widely regarded as retrograde. Such fortification with vitamin B_1 became unnecessary when the acute shortage of shipping space obliged the Government to abandon white flour in favour of National flour of not less than 85% extraction and including the maximum amount of wheat-germ. At the end of 1944, when the war in Europe was drawing to a close, it was found possible to reduce the extraction-rate to 80%; but this reduction could be justified by research which had shown that at this extraction flour could be milled which would contain most of the aneurine (thiamine), nicotinic acid, and iron. In January, 1945, the Ministry of Food convened a conference to advise on post-war bread policy and in particular on any regulations that might have to be made when wartime control ended. The members[3] included Lord Horder and the late Sir Jack Drummond, F.R.S., for the Ministry of Food, Sir Wilson Jameson for the Ministry of Health, Sir Edward Mellanby, F.R.S., for the Medical Research Council, and Prof. E. C. Dodds, F.R.S., for the National Association of British and Irish Millers; and though their conclusions suggest compromise for the sake of unanimity they include some important statements. Members of the official side of the conference had made it clear, said the report, that "all flour sold in this country for human consumption should, if practicable, be subject to regulation, so as to maintain a desirable nutrient standard." They had reached this conclusion as a result of "the very definite view expressed by the official medical and scientific members of the conference that a return to white flour, such as was commonly in use before the war, would be thoroughly bad for the nation's health." These members of the conference had said emphatically that "if the extraction rate of flour falls below a certain level and nothing is done to replace the lost nutrients, human beings dependent on bread for a supply of these nutrients are likely to suffer in health." "Limiting consideration to what is desirable and ignoring whether it is practicable or enforceable," the conference was not prepared to differ from the view that "natural food is to be preferred to food reinforced with so-called synthetic vitamins." The official scientific and medical members considered "that the retention of the natural constituents of the wheat grain is so incomparably preferable to reinforcement that they are not prepared to contemplate the adoption of" reinforcement. The conference was unanimous in recommending that it would be practicable for regulations to provide that flour (per 100 g.) should contain not less than the following amounts of three "token" nutrients: thiamine, 0·24 mg.; nicotinic acid, 1·60 mg.; iron, 1·65 mg.

In contrast to the uninstructed haste of 1918, the arrangements now being made for returning to white bread are cautious and complex. At the coming harvest, we are told,[4] the controls on cereals will be removed, the existing subsidy on flour will cease, and there will be an end to the restrictions on the type of flour which may be produced; but a National flour of 80% extraction is still to be available, and bread made from this will presumably be cheaper because it will be subsidised and subject to price control. Moreover, as a concession to nutritionists, the white flour of lower extraction is to have some of its deficiencies made good.

> "This whiter flour will . . . be fortified by the addition of nutrients equivalent to those lost in the further refining which it undergoes (so far as these can at present be identified) as well as the calcium which is already added to the National flour; and this will ensure that freedom to produce whatever flour the public prefers will not result in any avoidable lowering of nutritional standards."

But is there in fact any intention to add more than the three "token" nutrients—thiamine, nicotinic ous devices to keep particular muscle groups exercised, or to the warm plunge-bath, where physiotherapists exhort and persuade the gaily clad bathers to achieve the next stage of activity, or to the gymnasium, where the instructor notes with pride the gain in power of limbs impaired by poliomyelitis or other disorder From 4 30 to 9 30 P M the patients are off duty They can have tea in the handsome lounge, rest and read in the quiet room, chat or play games in the common-room, walk in the grounds, go out and visit friends, or join in the programme arranged by their own entertainments committee On three evenings a week the education and recreation department provides programmes of documentary and instructional films, or arranges discussions, games, or plays by local amateur dramatic societies or by the patients themselves All the patients have physical disabilities Treatment for industrial patients with neuroses is, of course, available at Roffey Park, near Horsham The average stay at Farnham Park is four weeks—the longest ten weeks The food is very good, and so is the morale of the patients, perhaps the two are linked

The Slough Industrial Health Service is thus a comprehensive scheme for the welfare of workers in industry, and has already shown its member firms a good return in the saving of working-time The workers themselves at first regarded it with the customary scepticism of the British working man, who is always wary of institutions outspokenly designed to do him good Gradually, however, they have come to recognise the value of the service, and now make full use of it

SCURVY

The Edinburgh Meeting

As already recorded in these pages, the Royal College of Physicians of Edinburgh and the Nutrition Society combined during the weekend of May 22 to celebrate in Edinburgh the bicentenary of the publication of Lind's *Treatise of the Scurvy*[1]

The proceedings opened with a "special graduation ceremonial" at which the Vice Chancellor (Sir Edward Appleton, F R S) conferred the honorary degree of doctor of laws upon Surgeon Vice-Admiral Sir **SHELDON DUDLEY**, F R S In a fighting speech Sir Sheldon said that the medical officer in the Royal Navy must educate his executive superior in practical hygiene, and that the importance of this subject was so great that there should be a health officer on the Board of Admiralty There was, he declared, no such entity as subclinical scurvy, and he believed that less than 15 mg daily of ascorbic acid was a maintenance dose although during the war dietitians had tried to persuade him that the figure was 300 mg At the conclusion of the ceremony a bronze plaque commemorating Lind was unveiled, the gift of the Sunkist Growers of Citrus Fruit in California and Arizona Later in the day another formal speech was made—this time by Prof V P **SYDENSTRICKER** (Augusta, Georgia), who gave the Sydney Watson Smith lecture in the Royal College of Physicians on the Impact of Vitamin Research on the Practice of Medicine

* * *

The scientific meetings of the Nutrition Society were opened by Sir **EDWARD MELLANBY**, F.R S, who stated that Lind was the first to introduce the experimental method into medicine He cruised in safer waters when he came to contemporary history and reminded us of the service Sir Sheldon Dudley had performed in establishing the Royal Naval Personnel Research Committee, and of the careful researches on nutrition of Dame Harriette Chick over many years, he and she were the only two surviving members of the original Accessory Food Factors Committee set up jointly in 1917 by the Medical Research Committee and the Lister Institute Dame **HARRIETTE CHICK** then reviewed the early investigations of scurvy and incidentally differed from Sir Sheldon in affirming the existence of the prescorbutic state Later in the symposium a paper on authors on scurvy before Lind was read on behalf of Mr A J **LORENZ**

Perhaps the most important contribution of the session was given by Mr C G **KING**, PH D (Nutrition Foundation, New York City), who by labelling compounds with ^{14}C has indicated how L-ascorbic acid is formed in the body of the rat from D-glucose, D-glucuronic acid being an intermediate He has also made the interesting observation that with deficiency of ascorbic acid there is an increased formation of cholesterol from acetate, but, although he is a champion of high human allowances of ascorbic acid, he was careful not to claim that ingestion of the vitamin would decrease atherosclerosis

This relation to cholesterol metabolism is possibly related to one of the most interesting aspects of ascorbic acid, its connection with the adrenal cortex Ascorbic acid may form as much as 4% of the dry weight of the adrenal cortex, and the vitamin was of course initially isolated from adrenals by Szent-Györgyi in 1927 Sayers[2] and his colleagues have shown that adrenal ascorbate is reduced by corticotrophin (A C T H) or by various stresses It is possible that an oxidation product of ascorbic acid is required for the synthesis of adrenal cortical hormone from cholesterol and it may be that corticotrophin promotes the oxidation of ascorbic acid Cornforth and Long[3] have suggested that cortisone promotes the peripheral oxidation of ascorbic acid

Prof R M **KARK** (Chicago) reviewed the relation of ascorbic acid to scurvy, corticotrophin, and surgery he claimed that there was no evidence that cold or adrenal cortical activity increases the human requirement of ascorbic acid, and he did not believe that ascorbic acid or a derivative of it is used in synthesising adrenal hormones

The Lind tradition of experimental work on man was upheld by papers from Dr J H **CRANDON** (Boston) and Prof H A **KREBS**, F R S Dr Crandon described the now classical experiment[4] in which he subsisted for six months on a diet containing no vitamin C subsequently he has investigated the relation of ascorbic acid to surgery Professor Krebs described the similar experiment later conducted in Sheffield on conscientious objectors[5] In the latter experiment a supplement of 10 mg of ascorbic acid daily was found to cure clinical scurvy in all six volunteers and protected three volunteers from scurvy for 424 days, this figure of 10 mg was somewhat arbitrarily trebled to arrive at a figure which would satisfy "ill-defined additional needs and to allow a margin of safety" Even this figure of 30 mg is of course very much lower than that required for saturation in a delightful paper Prof **GOUNELLE**, of Paris, informed the meeting that he had found that tuberculous prisoners-of-war did not become saturated until they were given 300 mg daily The question whether saturation is desirable or necessary was taken up by Dr King in the discussion at the end of the sessions when he defended the daily allowance of 75 mg of ascorbic acid recommended by the National Research Council Mr L J **HARRIS**, SC D, had suggested that the question of requirement was one that needed discussion and, after pronouncing himself in favour of saturation, he called on Dr King Dr **KING** said that 75 mg gave only half-saturation, the guineapig allowed to choose its diet kept itself saturated, and animals that synthesised their own ascorbic acid were saturated, it could be shown that guineapigs survived diphtheria toxin better on high levels (5–10 mg daily) than on lower levels (2–5 mg), even though these lower levels completely protected acid, and iron? Is riboflavine, for example, to be added? The Conference on the Post-War Loaf[3] appointed a subcommittee under Lord Horder's chairmanship which set the minimum for riboflavine at 0·14 mg. per 100 g. of flour—an amount unlikely to be included in flour of less than 80% extraction. Riboflavine is a nutrient "lost in the further refining" and "can . . . be identified"; it is clear therefore that it comes within the definition of required fortification. Pyridoxine and pantothenic acid could be supposed to come within it also; for both these substances are known to play a part in normal nutrition. Are pyridoxine and pantothenic acid, we may ask, to be restored in the quantities removed by the milling of white flour? If not, what nutrients "equivalent" to them are to be introduced, so that there shall be no "avoidable" lowering of standards? The truth is that, though the Government have explicitly stated that the white flour will be fortified with the identifiable nutrients lost in the further refining, there are grave doubts whether this will in practice be done. In the debate in the House of Lords last week Lord Carrington, for the Government, said that "the makers of whiter flour will be required to restore to that flour the same amounts of the main nutrients as are present in 80% extraction flour. The nutrients which will be put back are iron, vitamin B_1 and nicotinic acid." This statement conflicts with that in the white-paper on Decontrol of Cereals,[4] and it appears that the Government now intends to restore the same amounts of the *main* nutrients that are lost (iron, thiamine, and nicotinic acid), rather than all the identifiable nutrients that are lost. If so, the white bread will be *demonstrably* of lower nutritional value than the 80%-extraction National bread—quite apart from any deficiencies which may or may not exist in substances which the young science of nutrition does not yet recognise as significant. In times of poverty and scarcity, such as may lie ahead of us, good bread is the chief nutritional safeguard of Western peoples. Yet mainly, it seems, for the sake of economic or commercial convenience the public are once again to be encouraged to cultivate a taste for an inferior product.

In his Sanderson-Wells lecture which we publish this week, Professor Dodds launches a brilliant counter-attack against those of us who demand "natural" food. Certainly few would nowadays care to maintain that the seeds of wheat, maize, and rice were primarily and perfectly devised for the nutrition of mankind and must therefore be eaten exactly as provided by Nature. Most of us, when driven by his arguments, will go so far as to agree with Professor Dodds that in the modern world wheat and the like should not be regarded as sacrosanct entities but rather as food materials to be adapted to our purposes as may seem best for the satisfaction or preservation of our urban communities. Even so, having lived satisfactorily on natural foods for hundreds of thousands of years, we may fairly plead for the least possible interference with their character. Professor Dodds can easily persuade us that refrigeration, or heating, or sterilisation are essential; but it is a sound instinct that makes us unwilling to accept the chemical treatment of food as comparable with these traditional physical methods. Moreover, food chemistry is a new technique, and even the kind of elaborate animal experiments that Professor Dodds envisages would be a sketchy basis for chemical alteration of any of the basic nutrients of a nation. All sensible people will accept what is necessary; but the duty of proving that some chemical must be added to a traditional food rests squarely on the people who add it and the Government who authorise its addition. As regards the agene treatment of flour, this duty remains undischarged[5]; and the speech of the Government spokesman in the Lords reflects once again an attitude which Sir Edward Mellanby described two years ago[5A] as "disturbing, not only in itself, but because it indicates a reluctance to consider seriously the wider problem of chemical manipulation of food and its relation to health and disease."

Hazards of Phenylbutazone Treatment

Since the encouraging first reports by Currie[6,7] of the clinical use of 1 : 2-diphenyl-3 : 5-dioxo-4-*n*-butylpyrazolidine (phenylbutazone, 'Butazolidin') in the treatment of rheumatoid arthritis it has been widely used, both here and in America, against this and other rheumatic conditions, including ankylosing spondylitis, osteo-arthritis, and gout. Subsequent investigations[8,9] have confirmed the value of the drug in relieving symptoms, but have revealed a high incidence of toxic side-effects. Recent reports emphasise the more serious of these, and it is now clear that phenylbutazone can be dangerous. The physician, as so often happens, has to weigh advantage against risk.

The superiority claimed for phenylbutazone in the treatment of rheumatism lies in its analgesic property. In a discussion last week at the Royal Society of Medicine (reported on an earlier page) many physicians agreed on this point; and Dr. Freeland and his colleagues, whose article appears on p. 1227, offer further evidence of the subjective improvement induced by phenylbutazone in active rheumatoid arthritis. Objectively they find equally favourable results—although it should be noted that relief of pain may contribute to abatement of signs. It is clear that no permanent improvement is to be expected from phenylbutazone in rheumatoid arthritis. At the Royal Society of Medicine Dr. Rhys Davies showed that the grading of severity is not significantly affected by treatment. He is impressed, however, by the feeling of well-being induced in such cases by the relief of pain and by the accompanying functional improvement. Phenylbutazone may give this relief when other drugs have failed—a feature of undoubted importance to the patient. It is not seriously contended that phenylbutazone exerts any specific antirheumatic effect; no constant fall in sedimentation-rate accompanies its administration, and serial biopsy of rheumatoid nodules shows no change in the microscopic appearances.[10]

Dr. Freeland and his colleagues encountered no major toxic complications, perhaps owing to their prudence in stopping the drug in half the cases against scurvy After Professor **Kark** had made the observation that Gurkhas with low dietary levels of ascorbic acid had better physical achievements than a Harvard crew, Dr **King** emphasised that the National Research Council allowance should not be regarded as a "requirement", Prof E J. **Bigwood** (Brussels), however, equated "requirements" with "allowances" Mr A L **Bacharach** thought that the National Research Council figure ought to be high, because if it applied to foods as purchased there could be losses in cooking, and if it applied to the average person there would be a frequency distribution about the mean and therefore about half the population would need more than the mean Dr **Harris** closed the discussion with the remark that we must agree to differ on the question of requirements

It may be noted, however, that the National Research Council figures are specifically stated to refer to the "content of foods as eaten and [they] do not allow for losses in storage, cooking, and serving", further they are "levels enough higher to cover substantially all individual variations in the requirements of normal people"

* * *

Lack of time for full discussion immediately after papers was the obvious defect of the symposium which had been otherwise excellently arranged by Mr C P **Stewart**, PH D, and Dr A P **Meiklejohn** This lack was most obvious in the case of a paper from Dr S B **Wolbach** (Boston, Mass) on the histology of scurvy, extracts of which were read in his absence

Wolbach's views are controversial, but could not be controverted The controversy concerns the nature of the defect in connective tissue in scurvy In the scorbutic animal fibroblasts produce a metachromatic-staining material containing polysaccharides, and collagen is not formed, it is not certain whether the defect is in extracellular gelation or in the production of a precursor or factor by connective tissue cells There seems little doubt that collagen can be maintained but not adequately formed in the scorbutic animal, and King[6] has shown that ascorbic acid is not part of the chondroitin sulphate or collagen molecule Wolbach believes the defect is not in the production of the precursor of collagen, but in the extracellular conversion of the precursor into collagen, he thinks[7] that the pink-staining amorphous extracellular material in scorbutic tissues is the precursor of collagen Follis,[8] however, showed that this material was not produced in the bone of scorbutic animals unless those bones are subjected to stress, he regards Wolbach's gelation theory as unproved Both schools regard the changes in bone, teeth, and gums in scurvy as secondary to the failure to form connective tissue This has been summarised by Meiklejohn, Passmore, and Stewart

> "Wolbach showed a loss of collagen from connective tissues and a disappearance of intercellular cement As a result the cells forming the walls of the capillary blood vessels fail to stick together and this gives rise to the characteristic hæmorrhages There is also defective formation of dentine in the teeth and of the special tissue (osteoid) responsible for the growth and repair of bones Thus the three outstanding anatomical lesions of scurvy—the hæmorrhages, the loosening of teeth, and the bony deformities—can be traced to a single cause the failure in the supply of collagen for maintenance of connective tissue and intercellular cement"[1]

Here we can see that the controversy is even broader than the precise defect in production of collagen for, first, it is generally believed that in scurvy there is no *loss* of collagen but a failure to form it (once formed it can be maintained), secondly, capillary *permeability* is probably a function of the intercellular cement and is independent of ascorbic acid, whereas capillary *strength* is often but not always decreased in scurvy since there is weakening of the collagen surrounding the capillary wall and no weakening of the wall itself the endothelial intercellular cement being normal in scurvy[9], thirdly, the defective formation of dentine has no causative relation with the loosening and shedding of the teeth in scurvy which Lind so graphically described

The biochemical lesion underlying these histological changes is not known Possibly ascorbic acid or its oxidation products are concerned in setting up -S S bonds that link the protein chains in collagen A most important metabolic defect in scurvy concerns the oxidation of tyrosine Sealock[10] showed in 1940 that the metabolism of this amino-acid was defective in scurvy, next year Levine[11] and his colleagues reported that premature infants fed on cow's milk, a diet high in protein and low in ascorbic acid, excreted large amounts of derivatives of tyrosine in the urine unless ascorbic acid was given

Dr W J **Darby** (Tennessee) discussed the relation of ascorbic acid to tyrosine and hæmopoietic vitamins He supported the view that both ascorbic acid and folic or folinic acid are concerned in the oxidation of *p* hydroxyphenylpyruvic acid to 2, 5 dihydroxyphenylpyruvic acid which is then decarboxylated to give homogentisic acid he also supported the need of ascorbic acid for the conversion of folic to folinic acid

In the last year or two the stages in the oxidation of tyrosine through the compounds just mentioned have been elucidated and, although it is not certain that folic acid plays any part in them, ascorbic acid or its oxidation products are known to be concerned in the oxidation of *p* hydroxyphenylpyruvic acid and possibly in the later oxidation of homogentisic acid These biochemical aspects should have been discussed and it was a pity that there was no time for discussing each paper after it was presented, the short and somewhat desultory discussion at the end of the sessions achieved little

* * *

But the meeting closed in the evening with an excellent dinner that included scurvy-grass, adrenal cortices, and paprika, a dietitian expressed herself satisfied that the vitamin C content of the meal reached at least the 75 mg recommended by the National Research Council Here there was some confusion of sex, for the figure of 75 mg relates to men, but this confusion was perhaps started by Sir Edward Appleton who at the opening ceremony spoke of "the dietitian himself", and a few minutes later one wondered whether the dietitians who had pressed 300 mg daily on Sir Sheldon Dudley were male and if so were in fact dietitians But the presence of one of the four honorary members of the Nutrition Society at the dinner (Dame Harriette Chick) reminded us that excellent experimental work on vitamin C had during the past years been contributed by men and women working partly on guineapigs and partly on man This new knowledge is today applied in the prevention of scurvy in a way that would have satisfied Lind

H M S

CHILD HEALTH IN SCOTLAND

In 1949 a committee of the Scottish Health Services Council was set up, under the chairmanship of Mr Alexander Cunningham to review provision for child health in the country The committee has now reported,[12] and it suggests that the position should again be surveyed at the end of the first decade of the National Health Service

The committee urges the need for bringing together prevention and cure in all aspects of child care Other recommendations include the following

Antenatal period—In domiciliary practice there should be close coöperation between doctor and midwife and health

showing side-effects. Among the serious complications are sodium and water retention, leading to œdema; bleeding from the intestinal tract; and granulopenia. How far these are due to direct toxic action on tissues, and how far to acquired sensitivity is not known. Withdrawal of the drug may reverse the progress of complications; but at least 4 deaths from agranulocytosis attributable to phenylbutazone have been reported,[11] and the case described this week by Dr. DILLING adds another to this total. If granulopenia is a manifestation of drug allergy—and with amidopyrine (to which phenylbutazone is chemically related) this is probably so [12]—prolonged or repeated treatment may be expected to favour its occurrence. How this aspect of sensitisation is related to dosage is not known.

In these circumstances phenylbutazone should not be used merely as an alternative analgesic in rheumatism. Careful selection of patients and close attention to signs of toxicity are now rightly demanded [13]; and it is questionable whether these conditions can be fulfilled without hospital supervision.

Chemotherapy of Cancer

ADVANCES in chemotherapy of cancer have been slight in the past ten years,[14] save in the number of compounds tested, which now exceed 10,000. The sole gains relate to what is termed "management" in some forms of the disease, and to a little prolongation of something more than the mere spark of life in others. GELLHORN [15] has lately reviewed the most recent applications of chemical and hormone therapy based on extensive trials in man. The ideal would be chemicals with selective toxicity for tumour cells, leaving those of the host undamaged. This ideal is not yet in sight; for each of the effective chemical compounds is destructive to both. In judging the value of palliative drugs GELLHORN rightly insists on objective indices, such as fluctuation in size of lymph-nodes, fall in temperature, and restoration towards normal character and number of blood-cells. None of these criteria are applicable, however, to the largest group of tumours—those derived from epithelium.

Opinion about the value of œstrogens in breast cancer remains unchanged. As WALPOLE and PATERSON [16] suggest, their use should be limited to postmenopausal patients. Modifications in treatment of prostatic and mammary cancer have lately been summarised.[17] Adrenalectomy, combined with ovariectomy in the female, and cortisone substitution are being tried by HUGGINS.[18] This may be valuable when a tumour is adrenal-dependent, but dependence cannot be predicted before operation. In the late stages of lymphosarcoma and Hodgkin's disease cortisone and corticotrophin (A.C.T.H.) may bring the temperature back to normal and increase appetite; and bone-marrow function sometimes improves. The high hopes that these compounds would prolong life have not been realised: in acute leukæmia in children the prolongation of life is very small. Urethane is of use in chronic leukæmias when radiotherapy is contra-indicated or not available. Remissions lasting several months occur in about 30% of cases of acute leukæmia of childhood treated with modifications of folic acid (the anti-folic-acid chemicals aminopterin and A-methopterin); the median duration of life in those with remissions is twelve months, and further courses of treatment are progressively less effective. In the adult the disease is not modified at all. This disappointing outcome is in accordance with a previous forecast.[19] These drugs may be exceedingly toxic to normal blood-cells and to epithelium—more so, perhaps, than to the leukæmic cells, at least some of which eventually become drug-resistant. Refractoriness to these compounds and to cortisone and corticotrophin is, however, unrelated, so alternation in their use is worth a trial.

In Hodgkin's disease, in chronic leukæmias,[20] and to a less extent in disseminated lymphosarcoma, the nitrogen-mustard group of compounds is considered useful. When HN_2 is combined with radiotherapy the amount of irradiation required is materially reduced; patients remain symptom-free for the greater part of the treatment; and the burden of the illness is also significantly lessened owing to shorter periods in hospital and fewer applications of radiotherapy. The only other tumours which have responded to nitrogen mustards with sufficient regularity are bronchogenic carcinomas. Brief remissions of signs and symptoms, lasting two weeks to two months, have been induced. Similar or even longer remissions have been seen with X-ray therapy combined with administration of synthetic vitamin-K substitute ('Synkavit') in various tumours.[21]

There is something to be said for GELLHORN's suggestion that anti-tumour drugs should be screened clinically if and when criteria become available for measuring effects on tumours, especially those of epithelial origin. But not everyone will agree with some of his reasons. Experience has shown that there may be as much biological difference in behaviour between one human tumour and another at the same site as there is between similar animal and human tumours. Some respond to treatment while others, apparently identical, do not. Growth-rates of tumours, said to be so different in animals and man, must be related to the life-span of each species: the physiological events of three-score years and ten are crowded into the two and a half to three years of a mouse's life. Nor is it true that all animal tumours grow rapidly. Human tumours were always test objects for Coley's fluid and similar crude bacterial products [22] until SHEAR [23] with others identified the active necrotising agent in these products as a polysaccharide. Its action was analysed in animals, and has been ascribed to a capacity for inducing local hæmorrhage and thus inanition of the tumour. Against human tumours its performance has proved no better than in animals.[24] Keenly conducted screening techniques will take all these points into consideration.

visitor, where the last is not also the midwife, and the midwife should attend antenatal consultations. In some rural areas there may be room for more development of consultation clinics at which the general practitioner, the midwife, and the obstetric consultant should be present.

Neonatal period.—Special records should be kept of the condition of newborn infants, whether born in hospital or at home. The midwife engaged in domiciliary work should be able to detect conditions in the infant requiring medical attention. All maternity hospitals and maternity units of general hospitals should have special accommodation for sick, injured, and premature infants, and for isolation. Infants in maternity units should be under the care of a pædiatrician assisted by a house officer and, in a large unit, a registrar.

Child aged one month to one year.—Medical students should receive more instruction in infant hygiene and clinical pædiatrics, and general practitioners should attend refresher courses.

Pre-school child.—More advantage should be taken of the child welfare services by children of this age.

Child of school age.—A separate chief executive school medical officer should be nominated in the more populous counties. There should be an annual classroom inspection of all children who do not receive routine medical inspection during the year. The extent to which greater responsibility can be given to school nurses should be considered, and adequate clerical assistance should be provided for both medical and nursing staff.

Hospital and specialist services.—More bed accommodation should be provided, and the number of consultant pædiatricians should be increased. There should be interchange between clinical pædiatricians and medical officers engaged in child welfare work.

Integration.—In populous areas the child welfare clinic is essential. The coöperation of the consultant pædiatrician should be enlisted in the work of the welfare centres. The health visitor should play an important part in securing proper liaison between all parts of the National Health Service in relation to children. Where possible, institutes of child health should be established in which undergraduate and postgraduate training in pædiatrics could be undertaken.

MECHANICAL RESPIRATORS

The Ministry of Health, in a circular to hospital authorities (R.H.B. [53] 56), remarks that a working party has for some time been investigating problems connected with respirators. As a result a draft performance specification has been drawn up with which future respirators should comply.

Two entirely new respirators have been produced commercially, and have been approved by the working party. The cost of each will be about £800–1000; only a few will be available until 1954. Investigations are continuing into the development of a cuirass-type respirator, and of a simpler and cheaper cabinet respirator.

The working party has modified the Both respirator to make it more efficient. For this modification kits of manufactured parts are to be made available, and the work can be done by hospital engineers with simple tools. The cost of the kit is expected to be about £100. The changes, which agree closely with those devised in the Birmingham region,[1] are as follows:

Pump unit.—(1) a stronger motor platform; (2) a five step pulley pair; (3) improved bellows guides; (4) improved bellows, with extension pieces; (5) improved positive-pressure valve; and (6) improved hand-pumping gear.

Cabinet.—(a) Four arm ports each side of the body, one included in a bedpan port; (b) large window fitted into the top of the cabinet near the head end, the existing circular window being moved down towards the foot end; (c) alarm system, battery operated; (d) improved negative pressure valve fitted with friction stop and engraved calibration; (e) dial type aneroid pressure indicator; (f) improved body tilting gear; (g) raising the bed height and making the body unit mobile by fitting castors and brakes; (h) providing screws for tilting or raising the head end of the mattress; (i) providing a foot board; and (j) improved stretcher bearing roller.

It is likely that a split front and split collar will be recommended later when the parts become available. Meanwhile hospital authorities are asked to notify the Ministry without delay of the number of kits required.

The circular remarks that as an emergency measure the Both respirator may be further modified to make postural drainage possible. The patient is placed supine in a respirator of which the sloping front has been cut away vertically and replaced in this position with rubber seal and clips and head support.

The Wider World

THE HEALTH OF A TROPICAL PEOPLE

A Survey in Ceylon

H. CULLUMBINE
M.D., M.Sc. Sheff.
LATE PROFESSOR OF PHYSIOLOGY AND PHARMACOLOGY,
UNIVERSITY OF CEYLON, COLOMBO

IV. EASTERN AND WESTERN MEDICINE

The people of Ceylon have the choice of receiving their medical treatment from practitioners trained in either the Western or the Eastern systems of medicine.

The practitioners of the Eastern systems (in the following called Ayurvedic practitioners for convenience) include those trained in the Ayurvedic system, the methods of Siddha, and the Unani system. The practitioners of the Western system include, in Ceylon, graduates in medicine of recognised universities or medical colleges (in the following called Western practitioners), apothecaries in the Government service who have received a two year training in elementary medicine and, to relieve the shortage of fully trained Western practitioners, are attached mainly to out station, rural hospitals and dispensaries, and dispensers who have received some training in pharmacy and are to be found in charge of estate dispensaries.

Preferences of the People

The sample survey conducted in Ceylon in 1950 gave a general idea of the types of medical attention received by Ceylonese patients. It was based on door-to-door interviewing of 17,946 households, with 94,128 persons, from all districts, communities, and ethnic groups (Cullumbine 1952a), and one of the questions related to the nature of the medical care which was being given to the ill or disabled persons.

Western practitioners and Ayurvedic practitioners each treated a little over a quarter of the illnesses reported by the sample population. About 1 in every 20 sick people were receiving treatment from both types of practitioners and about 1 in 7 were not receiving any kind of specialised treatment (Cullumbine 1952b).

In general, Western practitioners treated a greater proportion of cases in the more serious diseases such as typhoid fever, tuberculosis of the respiratory system, malaria, dysentery, diseases of the circulatory system, bronchitis, pneumonia, and diseases of the genito-urinary system. By contrast, more cases due to the common cold, diarrhœa, dyspepsia, hæmorrhoids, deficiency diseases, rheumatic diseases, diseases of the skin, and conjunctivitis were treated by Ayurvedic practitioners. Western practitioners were, however, in charge of more of the normal and abnormal gestations, and this may be due to this provision of an antenatal and maternity service by the Government Medical Service. Illnesses of doubtful ætiology (e.g., the various mental disorders, paralyses, epilepsy, convulsions in children under 5 years) or illnesses which are refractory to treatment (e.g., the rheumatic diseases) received more attention from the Ayurvedic than from the Western practitioner. These were also the illnesses—along with tuberculosis, diseases of the genitals, and senility, all of

Annotations

EXPERIMENTAL INJURIES OF THE SPINAL CORD

It is generally recognised that in spinal injuries with involvement of the cord, damage to the cord occurs at the time of the injury, and that only in rare instances is it the result of continuing compression. For this reason, and because of the disappointing results of laminectomy in these cases, operative exposure of the cord is rarely carried out in the early stages of closed injuries; and in the later stages there is seldom much to be achieved by operation, except in the occasional patient where early improvement has given place to progressive impairment of cord function. Freeman and Wright[1] have investigated the question of spinal-cord damage experimentally, and they have produced evidence that, under the artificial conditions of their animal experiments, immediate operation on the cord may result in definite preservation of spinal-cord function. There is considerable difficulty in applying a standardised form of injury to the cord which can be reproduced in a series of experiments, and Freeman and Wright finally decided that direct, rather than indirect, trauma would be the most suitable. Their preliminary experiments were performed on rats. The spinal cord was exposed in the mid-dorsal region and a lucite rod, concave at one end, was placed vertically on the cord. A glass tube was placed over this lucite impounder, and trauma was applied by a mercury-filled glass rod which was dropped through this glass tube on to the impounder; this method made it simple to vary the force applied in different experiments. Three series of rats were studied: in one group a laminectomy alone was performed; in the second trauma was applied following laminectomy; and in the third group, immediately after the trauma, the pia mater was incised and an incision was made in the midline of the posterior aspect of the cord and extended for the length of the laminectomy through approximately half the thickness of the cord. With a force of 25 g. cm., paraplegia could be produced in the rats; and when they were studied for up to three weeks after trauma, recovery was commoner in the animals in which the pia had been opened and a blunt myelotomy performed.

These results suggested that operation might be helpful in diminishing the effects of the cord injury, so further studies were made on dogs. The experimental procedure used in two groups of dogs was the same as in the rat experiments, except that a force of about 400 g. cm. was used, and in the operation group, following posterior myelotomy, a gentle stream of warm saline was directed into the incision in the cord and necrotic tissue was washed out. Of the 9 animals in which immediate operation was performed following the experimental injury, 3 recovered sufficiently to walk reasonably well within a few days to five weeks, and another regained some power in the hind legs; but there was no recovery of function in the animals in which the cord was injured and no further operation was performed. In a further series of dogs a rather different procedure was used: a single laminal arch was fractured with an osteotome and then swung to one side; the impounder was then inserted and the spinal cord was injured as in the previous experiment. In the control group the lamina was replaced and the wound closed; and in the second group a formal laminectomy was carried out and the spinal cord was treated operatively as in the earlier experiments. In the control group only 4 out of 12 animals regained any function, and, of these, 2 were severely incapacitated: while in the operated group 8 out of 10 showed some degree of functional recovery. These results suggest that operation immediately after injury is of benefit in preserving some degree of spinal-cord function in a proportion of the animals, and Freeman and Wright propose to carry out further experiments to find out how long after injury operation can be delayed. The direct trauma used in these animal experiments is not really comparable with the indirect trauma which commonly causes spinal injuries in man; but if further work confirms these findings, early operation, by incision of the pia and posterior myelotomy, must be considered as a possible treatment of spinal injuries in man.

AN ANTIVIRAL SUBSTANCE

Hitherto the small viruses have been rather inaccessible to chemotherapeutic agents, so it is interesting to read a report by Shope[1] on an antiviral substance derived from *Penicillium funiculosum* (Thom). The active material, which he has called helenine, showed slight but definite antiviral action when tested against two neurotropic viruses—the Columbia SK encephalomyelitis virus of mice and the Semliki Forest virus. In early experiments slight activity against swine-influenza virus was noted, but this result could not be reproduced later. Helenine was most readily obtained by mechanical bruising in a Waring blendor of the pellicle formed in *P. funiculosum* cultures, followed by solution in culture fluid and precipitation by acetone. Its effect was most obvious when it was given in one or two injections from a few hours before until twenty-four hours after infection with 10 to 1000 minimal lethal doses of virus. Under favourable conditions helenine protected up to about half the treated mice or caused a significant delay in death. Its mode of action is not clear, but it seems either to slow the rate of virus multiplication or to prevent invasion of the mouse brain; for in the early stages of infection there was less virus in the brains of the treated animals than in the controls. Little is known of its chemistry, but extracts are viscous and contain a high proportion of polysaccharide.[2]

Shope tells us that the penicillium was recovered from the isinglass cover of a photograph of his wife, Helen—hence the name helenine. This method of naming chemotherapeutic substances is unusual and might cause difficulties if a mould happened to lodge on a *View of Battersea Power Station from Chelsea Bridge*, for example. But this is a matter which can safely be left to the nomenclature committees of the next Microbiological Congress, with perhaps a little assistance from the Royal Academy.

COLOURED NAILS

It is refreshing to read a description of a clinical investigation made without elaborate equipment. For centuries white spots on the nails have been found puzzling. They have their own folklore and an extensive medical "literature." Only now has an observer had the patience to study their natural history. Mitchell[3] charted the position of white spots on his nails daily for a year. He discovered that such spots not only may appear for the first time in the distal part of the nail, but may enlarge or disappear before the growth of the nail carries them to the free edge.

These white spots have commonly been ascribed to air-spaces in the nail, caused by small areas of imperfect cornification due to local or general disturbances affecting the nail matrix. The appearance of white spots in the distal portion of the nail suggests that the distal nail-bed may participate in the formation of the nail-plate. Many deny this, yet histological evidence supports the possibility. Nail and hair cortex are formed without the against scurvy After Professor **KARK** had made the observation that Gurkhas with low dietary levels of ascorbic acid had better physical achievements than a Harvard crew, Dr **KING** emphasised that the National Research Council allowance should not be regarded as a "requirement", Prof E J. **BIGWOOD** (Brussels), however, equated "requirements" with "allowances" Mr A L **BACHARACH** thought that the National Research Council figure ought to be high, because if it applied to foods as purchased there could be losses in cooking, and if it applied to the average person there would be a frequency distribution about the mean and therefore about half the population would need more than the mean Dr **HARRIS** closed the discussion with the remark that we must agree to differ on the question of requirements

[3] Mitchell, J. C. *Brit. J. Derm.* 1953, 65, 121.

It may be noted, however, that the National Research Council figures are specifically stated to refer to the "content of foods as eaten and [they] do not allow for losses in storage, cooking, and serving", further they are "levels enough higher to cover substantially all individual variations in the requirements of normal people"

* * *

Lack of time for full discussion immediately after papers was the obvious defect of the symposium which had been otherwise excellently arranged by Mr C P **STEWART**, PH D, and Dr A P **MEIKLEJOHN** This lack was most obvious in the case of a paper from Dr S B **WOLBACH** (Boston, Mass) on the histology of scurvy, extracts of which were read in his absence

Wolbach's views are controversial, but could not be controverted The controversy concerns the nature of the defect in connective tissue in scurvy In the scorbutic animal fibroblasts produce a metachromatic-staining material containing polysaccharides, and collagen is not formed, it is not certain whether the defect is in extracellular gelation or in the production of a precursor or factor by connective tissue cells There seems little doubt that collagen can be maintained but not adequately formed in the scorbutic animal, and King [6] has shown that ascorbic acid is not part of the chondroitin sulphate or collagen molecule Wolbach believes the defect is not in the production of the precursor of collagen, but in the extracellular conversion of the precursor into collagen, he thinks [7] that the pink-staining amorphous extracellular material in scorbutic tissues is the precursor of collagen Follis,[8] however, showed that this material was not produced in the bone of scorbutic animals unless those bones are subjected to stress, he regards Wolbach's gelation theory as unproved Both schools regard the changes in bone, teeth, and gums in scurvy as secondary to the failure to form connective tissue This has been summarised by Meiklejohn, Passmore, and Stewart

> "Wolbach showed a loss of collagen from connective tissues and a disappearance of intercellular cement As a result the cells forming the walls of the capillary blood vessels fail to stick together and thus gives rise to the characteristic hæmorrhages There is also defective formation of dentine in the teeth and of the special tissue (osteoid) responsible for the growth and repair of bones Thus the three outstanding anatomical lesions of scurvy—the hæmorrhages, the loosening of teeth, and the bony deformities—can be traced to a single cause the failure in the supply of collagen for maintenance of connective tissue and intercellular cement"[1]

Here we can see that the controversy is even broader than the precise defect in production of collagen, for, first, it is generally believed that in scurvy there is no *loss* of collagen but a failure to form it (once formed it can be maintained), secondly, capillary *permeability* is probably a function of the intercellular cement and is independent of ascorbic acid, whereas capillary *strength* is often but not always decreased in scurvy since there is weakening of the collagen surrounding the capillary wall and no weakening of the wall itself the endothelial intercellular cement being normal in scurvy [9], thirdly the defective formation of dentine has no causative relation with the loosening and shedding of the teeth in scurvy which Lind so graphically described

The biochemical lesion underlying these histological changes is not known Possibly ascorbic acid or its oxidation products are concerned in setting up -S S bonds that link the protein chains in collagen A most important metabolic defect in scurvy concerns the oxidation of tyrosine Sealock [10] showed in 1940 that the metabolism of this amino acid was defective in scurvy, next year Levine [11] and his colleagues reported that premature infants fed on cow's milk, a diet high in protein and low in ascorbic acid, excreted large amounts of derivatives of tyrosine in the urine unless ascorbic acid was given

Dr W J **DARBY** (Tennessee) discussed the relation of ascorbic acid to tyrosine and hæmopoietic vitamins He supported the view that both ascorbic acid and folic or folinic acid are concerned in the oxidation of *p* hydroxyphenylpyruvic acid to 2, 5 dihydroxyphenylpyruvic acid which is then decarboxylated to give homogentisic acid he also supported the need of ascorbic acid for the conversion of folic to folinic acid

In the last year or two the stages in the oxidation of tyrosine through the compounds just mentioned have been elucidated and, although it is not certain that folic acid plays any part in them, ascorbic acid or its oxidation products are known to be concerned in the oxidation of *p* hydroxyphenylpyruvic acid and possibly in the later oxidation of homogentisic acid These biochemical aspects should have been discussed and it was a pity that there was no time for discussing each paper after it was presented, the short and somewhat desultory discussion at the end of the sessions achieved little

* * *

But the meeting closed in the evening with an excellent dinner that included scurvy-grass, adrenal cortices, and paprika, a dietitian expressed herself satisfied that the vitamin-C content of the meal reached at least the 75 mg recommended by the National Research Council Here there was some confusion of sex, for the figure of 75 mg relates to men, but this confusion was perhaps started by Sir Edward Appleton who at the opening ceremony spoke of "the dietitian himself", and a few minutes later one wondered whether the dietitians who had pressed 300 mg daily on Sir Sheldon Dudley were male and if so were in fact dietitians But the presence of one of the four honorary members of the Nutrition Society at the dinner (Dame Harriette Chick) reminded us that excellent experimental work on vitamin C had during the past years been contributed by men and women working partly on guineapigs and partly on man This now knowledge is today applied in the prevention of scurvy in a way that would have satisfied Lind

CHILD HEALTH IN SCOTLAND

IN 1949 a committee of the Scottish Health Service Council was set up, under the chairmanship of Mr Alexander Cunningham to review provision for child health in the country The committee has now reported,[1] and it suggests that the position should again be surveyed at the end of the first decade of the National Health Service

The committee urges the need for bringing together prevention and cure in all aspects of child care Other recommendations include the following

Antenatal period—In domiciliary practice there should be close coöperation between doctor and midwife and health

production of keratohyalin, and the "hard keratin" which results has physical and chemical peculiarities. The distal nail-bed as well as the matrix has no granular layer, and unless it were "onychogenic" one would expect to find it giving rise to parakeratotic horn, which is friable. The enlargement and disappearance of these spots are less easily explained if they are due to structural changes in the nail, since one must then assume that fully formed nail is still alive. If the white spots were due to foci of parakeratosis it seems most improbable that this could be altered to give rise to normal nail.

White spots are common in normal people but are apparently confined to the finger-nails. They may be congenital and affect a single nail or part of a nail. Disorders to which leukonychia has been ascribed include psoriasis, leprosy, fevers, arsenic and thallium poisoning, fluorosis, and trichinosis. The common disorders of the nails—psoriasis, eczema, and fungus infections—usually discolour the nails yellow, brown, or black. With subungual hæmorrhage the nail is blue or black. An unfamiliar cause of such hæmorrhage is epidermal hypersensitivity provoked by "undercoats" applied to render nail-varnish more permanent. Argyria causes bluish-violet coloration of the nails; and a fixed drug eruption due, for example, to phenolphthalein may appear in the nail-bed as a dusky erythematous patch. Violaceous bands have been seen in congenital syphilis; and those who served in the Far East in the late war became accustomed to a purplish discoloration of the nail-bed in men who were taking mepacrine prophylactically. Green nails have been attributed to infection with common skin fungi or to superinfection with *Pseudomonas aeruginosa*. Heller [4] lists as occupational stigmata green nails in pea-shellers, red nails in vineyard workers, and black nails in feltmakers; and he has seen blackish-brown nails in April to June, due to exposure to formic acid, in "seekers after ants' eggs."

ASSESSMENT OF LEUCOTOMY

Prefrontal leucotomy should be a convenient meeting-ground for clinician and experimental psychologist. By providing what is practically an experimental incision into the frontal lobe it has challenged the ingenuity of the research-worker to uncover the functions of a part of the brain of which little is known with precision. At first this ingenuity was limited to speculation, and "a skyscraper of theory was erected on an unstable foundation of insufficient fact" [5]; but when the experimental psychologist entered the field, the ingenuity was extended to method. One American worker, who had complained that "not a single patient has been adequately studied," [6] produced a book [7] in which mathematical treatment ran riot; and the same line of approach is taken in an article by Le Beau and Petrie.[8] Giving brief statistical conclusions from the application of ten or more tests to 35 patients, who among them had some twelve different operative lesions, this work adds to the number of combinations of cuts, tests, and patients which Mrs. Petrie described previously.[9] The risk in such work, however, is that zeal for objectivity may lead to a preoccupation with technique. The clinician, at least, is likely to find himself less interested in the test data than in the authors' observation (mentioned almost as an afterthought) on the patients' attitude to time. We know that after leucotomy some patients have an altered appreciation of time, and this is something not yet analysed. In relation to pain, Le Beau and Petrie say there is increased orientation to the present, as opposed to the past and future; the leucotomised patient contends with present pain only, thus making a long-continued pain more bearable. This touches one of the clinician's topical interests, and is the kind of observation that could be followed by an empirical investigation along traditional lines.

"Science," says Professor Zangwill, "aims at a quantitative treatment of its data, but the scientist should never allow himself to become bemused by the prestige of numbers." [10] "In studying problems of temperament," he continues, "it may well turn out that the descriptive method, despite its notable lack of precision, has the greater value. Empirical science is not in the first place a technique: it is an attitude of mind." To the clinician it must seem that what is needed for the assessment of leucotomy is the use of established case-history methods, but in a more controlled fashion than is commonly needed in clinical practice, combined (where appropriate) with a more generous and flexible use of psychometric tests.

TOXICITY OF CHLORAMPHENICOL

Administration of chloramphenicol may result in aplastic anæmia [11] or other side-effects, including anaphylactic reactions, cutaneous eruptions, moniliasis, and irritation of the mucous membranes. Lasky et al. [12] describe a case of bacterial endocarditis in which administration of 6 g. of the drug daily for six weeks led to severe anæmia followed by retinal hæmorrhages and bilateral optic neuritis. After the chloramphenicol was discontinued the anæmia disappeared, but the vision remained seriously and permanently affected. This report should not deter doctors from using chloramphenicol; for the dosage was very large, and the drug was given for a long period. It is well known that compounds containing a benzene ring with a nitro-group attached—as in chloramphenicol—are potentially toxic. In moderate dosage, and for short-term administration, chloramphenicol is safe enough; but the use of other antibiotics should always be considered if medication has to be long continued.

COUNTING BACTERIA

In microbiology it is often necessary to determine the number of living or dead bacteria contained in a fluid—for example, milk or a bacterial vaccine. The number of living organisms is usually estimated by counting the number of colonies which develop after a known volume of the fluid has been spread over a solid medium; while total bacteria, living or dead, are usually enumerated by comparing the fluid with tubes of standard opacity. Both these techniques are subject to various errors, and their use in assessing the proportion of living bacteria in a fluid is liable to be fraught with inaccuracy. Valentine and Bradfield [13] have now described an elegant and accurate method for determining the number of living and dead bacteria simultaneously. The method depends on the fact that 3% urea inhibits cell-division of certain organisms but does not affect cell-growth, so that living bacilli develop into long filaments, which can easily be distinguished microscopically from the normal-sized dead bacilli.

By this method a collodion film, supported on a stainless-steel specimen grid, is laid on to nutrient agar containing 3% urea. A drop of the fluid in which the bacteria are to be enumerated is placed on the collodion and the whole is incubated at 37°C for 3 hours. The grid is then fixed in osmium tetroxide or formalin vapour, washed in distilled water, dried, and examined with an electron microscope. The proportion of living organisms

medical services, including maternity. His application named his residence as the place where he would attend for treating health service patients and stated his proposed hours for the purpose. In the following month he was accordingly placed on the list, and he so continued, except that in November, 1951, his name was (by agreement) omitted from the separate part of the list which contains the names of those undertaking to provide maternity medical services. In the same month of November he notified the council of a change in his hours for treating patients which does not appear material to the findings. In June, 1949, he asked the council's permission for a grant for training Dr. P. as an assistant. This was sanctioned. From June to October he employed Dr. P. as his paid assistant. From Aug. 2 she was in effect conducting the practice at his residence by herself; on that date he took a whole-time appointment at the X hospital where he continued to serve (full time) till March 2, 1952. The tribunal found that he had at one stage suggested to Dr. P. that she should become his trainee assistant, but she never acted as such. He filled up a form (E.C. 45) stating that she so acted from July 1 to Sept. 30, and claiming £191 2*s.* with £40 19*s.* for boarding expenses. He asked Dr. P. to sign the form; she refused and sent the form unsigned to the council. Dr. M. and Dr. P. had a difference of opinion about his conduct of the practice, and in October he dismissed her from his service.

In November Dr. M. engaged Dr. W. as a trainee assistant and informed the council that he had done so. During 1950 he completed four quarterly claims for training grant, signing them and obtaining Dr. W.'s countersignature; on these claims he drew sums totalling £697 4*s.* 4*d.* From Oct. 10 to February, 1952, he employed her as an ordinary assistant. Dr. W. told the tribunal that she discussed cases with Dr. M. in the evenings (like Dr. P. she lodged in the house of Dr. and Mrs. M.), that she learnt a good deal from him, and that he did his best to supervise and train her. The tribunal has found, however, that he neither gave, nor was in a position to give, any sufficient training to Dr. W., as he was already employed in a whole-time hospital appointment elsewhere. The tribunal has no doubt that he committed a serious fraud upon the council by claiming and receiving sums of money, as he did, for training Dr. W. when he was engaged whole time at a hospital a considerable distance away from the place where the trainee assistant was employed.

The council received information from the Ministry of Health in November, 1951, about Dr. M.'s hospital appointment. His reply to the council's consequent inquiry referred to "my letter of the 7th October, 1950, explaining the position." As no such letter could be traced he was asked for a copy of it. The copy which he furnished stated that as from Oct. 10 Dr. W. would be acting as his full-time assistant, and that, unless he heard to the contrary, he would assume that the consent given for her to act as his trainee assistant would continue for her new status. The tribunal observed that a year earlier (and two months after the date of the missing letter) the council had asked Dr. M. to complete a return on which questions were asked as to his employment of an assistant and as to his own effective service under the National Health Service. Receiving no answer, the council drew his attention to his omission to complete the form and sent him a further questionary asking (among other things) if he employed an assistant and, if so, whom, and whether he was substantially employed on other work and, if so, what. To this he replied on Dec. 30, 1950, that he proposed to retire from the service on March 31, 1951; he asked that this letter should be accepted as notice of his intention.

The tribunal found no evidence that Dr. M. had written the letter of Oct. 7, 1950. They consider it quite untrue, and quite untrue to his knowledge, that he ever sent such a letter. They find that Dr. M. has "over a substantial period of time committed serious breaches of his terms of service . . . and has carefully taken deliberate steps to deceive [the council] as to the true state of affairs." He has "perpetrated a gross financial fraud" upon the council. Four witnesses, it is stated, were tendered to the tribunal by the complainant council; Dr. M. was present at the hearing but neither gave evidence himself nor called any witnesses.

While the onus must be upon the complainants to prove allegations which, if established, will affect the livelihood of a practitioner, it is difficult to see on what grounds the Minister could have reversed the tribunal's decision.

Parliament

Processed Foods

IN the House of Lords on June 10, Lord TEVIOT called attention to the high proportion of processed and chemically treated foods now consumed, and urged the Government to do everything possible to increase the availability of fresh food in the interests of public health. He said he was a trustee of what was perhaps the biggest clinic in the country and the number of people who came in for special diet there was very large. In the rise of agene, and other so-called improvers of bread, was to be found one of the great dangers to the general health of the people. He hoped that the Zuckerman Committee would go into the question whether poisonous sprays used on crops infiltrated into the human body. He had seen people who had eaten fruit that had been sprayed and who had undoubtedly been poisoned thereby. The late Sir Jack Drummond had once told him that if the people of this country could be fed on fresh home-grown and home-killed food he believed that in twenty years the hospitals would be nearly empty. It would be an advantage if school-children were told what they should eat and how they should eat it, instead of being lectured on sex. The degradation of our daily bread had reached a stage which made it vital that a halt should be called at once: the wheat germ and wheat-germ oil should never be taken out of bread. Summing up, Lord Teviot said that the comfort of our "tummies" greatly affected our point of view and attitude to everyday problems. In nearly every hotel in the country could be seen slot-machines containing stomach powders, aspirin tablets, and purgatives. Properly fed people did not need these drugs. Far too many people were making fortunes out of tampering with natural food, and there were far too many people making vast sums out of the antidotes to eating these bad foods.

THE DEBATE

Lord HANKEY, who had a motion on the paper urging the Government to reconsider the use of agene in flour for human consumption, explained that he would not move it until after the debate if necessary. In support of Lord Teviot's motion, he said that agene was a by-product of the white-bread complex which for 200 years had been the cause of much adulteration of food. It was not until the early 18th century that the popular craze for white food became serious. Until then it had been the luxury of the rich and the new craze started mainly in the towns; but, as the wheat crop was often insufficient to supply the need, the adulteration of bread followed. Alum, the principal improver for 100 years or more, was a double sulphate of aluminium and potash. It was found to be harmful to the internal organs and the townsfolk became afflicted by chronic dyspepsia, while their children were described as "pale, puny, lingering and sickly." But despite their sufferings, the warnings of doctors and scientists, and the repeated efforts of Parliament between 1750 and 1800 to foster the sale of standard bread, our people clung to their adulterated white bread as obstinately as they did today. What else could have been expected? There was no established principle to guide Governments. But in the 1850s, thanks largely to *The Lancet* and *Punch* (whose editors Lord Hankey hoped would take note)—*The Lancet* had already broken a lance on agene—the Government was goaded into action. After an official inquiry by a select Parliamentary Commission, remedial legislation was enacted, but often rather feebly administered. About the year 1877 a new trouble arose through the introduction of steel rollers to replace the old grindstones. The result was what the late Sir Jack Drummond called "poverty bread" because it had been robbed of its essential vitamins and minerals. Though it may have made fortunes for the trade, it completed the ruin of the nation's teeth. The tragedy of this "poverty bread" was that its dangers were unsuspected and were only discovered some 50 years later, about 1925, after the establishment of the Medical Research Council.

But the health aspect of white bread was still disregarded and, in spite of the improvement inaugurated by Lord Woolton during the war, the country was now is readily determined by a differential count of the numbers of filamentous and normal cells.

The method appears to give accurate results within the limits of normal sampling errors. It has its disadvantages, however. The use of an electron microscope is perhaps not essential, though it seems to provide the only reliable means of distinguishing between very short bacilli and particles of medium or detritus. Electron microscopy is also necessary if lysed cells are to be included in the count. The main disadvantage of the technique is that it cannot be used to count cocci, which do not develop into giant forms in the presence of urea, or organisms which normally contain filamentous cells. The organisms which have been counted successfully are various strains of bacterium, chromobacterium, pseudomonas, and a paracolon bacillus.

The usefulness of this method in routine work is clearly limited, but it may find a place in the armamentarium of the research-worker. Valentine and Bradfield have applied it successfully to the study of the resistance of bacteria to drying and also of the effects of radiations on bacterial cells.

MALIGNANT SYNOVIOMA

TUMOURS arising from synovial membrane were first described in 1910 by Lejars and Rubens-Duval.[1] Not all tumours in synovial tissue, however, are synoviomas; and de Santo et al.[2] have for this reason criticised the use of the term. Today "synoviomas" are known to fall into two groups—the malignant and the benign. Harkness,[3] Hale,[4] and others have emphasised that at operation the former may appear innocent.

In 47 examples of malignant synovioma collected by Wright,[5] close on three-quarters of the patients died of generalised metastases, with an average survival-time of twenty-three months. 10 are still alive today: 2 have survived twenty-four and thirteen years, while 4, though still alive after nine years, have had recurrences of the tumour. The findings of King[6] in a smaller series are substantially similar. The majority of the malignant tumours studied by Wright were devoid of giant-cells, but even in the most malignant of them synovial characters were recognisable: they were, therefore, essentially mixed tumours, and either the endothelial or the sarcomatous element preponderated—usually the former. In the well-differentiated and sometimes encapsulated forms of malignant synovioma, cavity formation was conspicuous; and then, but for the fact that the lining cells had no true border but merged imperceptibly with the diffusely arranged surrounding cells, their differentiation from true epithelial cells became somewhat difficult. The first of the 2 cases described by Harkness,[3] for instance, distinctly resembles a spheroidal-cell carcinoma of the breast, as also does the original case figured by Lejars and Rubens-Duval. Haagensen and Stout[7] illustrate in their series well-differentiated columnar cells. Carcinomatoid features in the malignant synovioma are paralleled in certain inflammatory states of synovial membrane by an exuberance of the endothelium with groups of spheroidal cells resembling epithelium. In the well-differentiated forms of malignant synovioma, sarcomatous and endothelial elements are usually equally prominent, the former being mainly spindle-cells with varying amounts of collagen. Mucin production is usual. Giant cells are occasionally seen in malignant synoviomas, and confusion may then arise with the benign variety; in Wright's experience, however, the malignant tumours are the more cellular and show fairly numerous foci of necrosis, mitoses, and a tendency to form synovial cavities. The only giant-cell synovial tumours which metastasised were distinctly anaplastic, and for that reason were readily recognised. Infiltration of muscle, however, was noted in one of the well-differentiated giant-cell tumours, so that their malignant character cannot be doubted.

Fisher,[8] de Santo et al.,[2] and King[6] have all built up their histological classifications on slightly different lines; but they recognise the essential unity of the malignant synovioma. King remarks that in assessing the malignancy of any particular tumour it is necessary to consider the characters of any group of rapidly growing cells rather than the general degree of differentiation found throughout the tumour. Metastases may be confined to the regional lymph-nodes but are apt to be widespread: the lungs and the bones are evidently common sites. Cases have been recorded where metastases developed seven, ten, and twelve years after amputation. Of Wright's series a definite history of local injury was obtained in 28%; but in only 1 of the 17 cases reported from the Massachusetts General Hospital by Hale[4] was there a reliable history of trauma. de Santo and his co-workers concluded that trauma occasionally initiated symptoms but by no means produced the tumour. Rarely, they thought, a chronic bursitis might predispose to the onset of a synovial sarcoma.

The commonest site of this tumour seems to be the lower limb, especially in the region of the knee. Fisher[8] drew attention to tumours histologically of the same pattern but occurring in the limbs outside joints and not in relation to bursæ or tendon-sheaths; while Haagensen and Stout[7] emphasised that often the tumour does not arise in actual synovial membrane. King[6] believes that, given the appropriate stimulus, connective-tissue cells anywhere are capable of the particular kind of differentiation found in synoviomas. The tissue-culture studies of Vaubel[9] show the potentialities of embryonic synovial tissue, especially histiocytic.

The radiographic findings are fairly characteristic but not diagnostic. A soft tissue mass in or near a joint, lobulated, often with a fine speckled type of calcium, and sometimes associated with periosteal proliferation, is suggestive of this disease.[4] For the encapsulated uniformly well-differentiated growths, Wright[5] regards local excision as adequate but in the poorly differentiated tumour amputation offers the only hope—and it is not a good one. The prognosis apparently depends more on histological structure than on the mode of surgical treatment. It is a disease more of the young than the old, the average age of the patients being lower than that of those with fascial and related sarcomata.[6] It has been recognised in a nine-month-old child in whom the history dated back to the age of two months.[10] In the Boston series females were more commonly affected than males; but in most other series males have predominated.

which may also be refractory to treatment—which showed the highest percentages of patients receiving both forms of treatment Patients with illnesses which Western medicine has shown that it can control are thus placed in the care of Western practitioners, where such a superiority on the part of Western medical science has still to be conclusively proved to the layman, then help from the traditional Ayurvedic system is sought (One possible and interesting exception to this is the observation that Ayurvedic practitioners treated more accident cases than did the Western practitioner)

It may, of course, be argued that the Ayurvedic practitioner treats more illnesses of doubtful ætiology because his lack of skill in modern diagnostic methods prevents his making a precise and understandable diagnosis This may be true, but it cannot be proved from the data provided by this survey For example, as many cases of ill defined cause were treated by Western as by Ayurvedic doctors (These illnesses with an ill-defined cause would include those sicknesses the cause of which the interviewed persons could not remember, as well as undiagnosed or not yet diagnosed cases)

Another factor which may influence the choice of treatment is the relative availability of the different practitioners On estates, where dispensers are stationed, these practitioners treat most of the illnesses Western doctors tend to be concentrated in urban areas, whereas in the rural areas, treatment by the Ayurvedic physician and the apothecary predominates

The lower the family income, too, the higher the proportion of cases treated by Ayurvedic practitioners This may be a direct influence of poverty or, it may be claimed, an indirect effect of the ignorance which is often associated with poverty

The type of medical attention received also varies to some extent with the duration of the illness (and therefore, as noted, with the cause of illness) The proportion of cases treated by Western practitioners increases with duration of illness up to 3 months and then decreases, Ayurvedic practitioners treat progressively smaller proportions of cases as duration of illness increases up to 28 days and then more of the longer duration cases receive this system of treatment This may be due to patients with different illnesses seeking different methods of treatment or may indicate a transference of the patient from Western to Eastern practitioner as the disease becomes chronic The latter explanation is supported by the fact that as duration of illness lengthens so the proportion of patients receiving attention from both Western and Ayurvedic practitioners progressively increases

As the age of the patient increases, so the proportion of illnesses receiving attention from Western practitioners or apothecaries or dispensers decreases, while relatively more illnesses are treated by Ayurvedic or by both Ayurvedic and Western practitioners This may be due to a combination of circumstances Older people may prefer the traditional Ayurvedic system or, because the incidence of chronic illness increases with age, more old patients seek Ayurvedic treatment

During infancy the majority of cases, irrespective of the duration of illness, are treated by Western practitioners, although as the duration increases so the proportion receiving skilled treatment decreases and the proportion treated only by relatives increases (Which is the cause and the effect in the latter is not certain)

During the pre school years again, Western practitioners are the most favoured with all durations of illness, although as the duration increases so relatively more cases are treated by Ayurvedic or both Ayurvedic and Western practitioners

For illnesses among school children Western practitioners treat the greater proportion for durations up to 3 months after which Ayurvedic treatment is the more readily sought

During the early and mid adult age periods, Ayurvedic practitioners are favoured for illnesses of short duration (7 days and less) The proportions of illnesses treated by relatives or by Western practitioners increase as the duration of illness increases, and the reverse is true for Ayurvedic practitioners

In the late adult and old ages as illness duration lengthens so more patients treat themselves or seek Ayurvedic or both Ayurvedic and Western treatment, and Ayurvedic is preferred irrespective of the duration of illness

The Future

On the whole the Ceylonese shows a reasonably intelligent approach to the new ideas of Western medicine He has accepted and demands those therapies which are known to be effective, for the rest he still turns to his traditional, conservative Ayurveda The expansion of international health services since the war has introduced modern medical techniques from the West into regions where only the ancient systems of medicine have been previously known The new ideas will be accepted only if and when they prove more efficacious than the old In addition there may be religious and cultural barriers to be overcome

It is difficult to assess the value of the indigenous systems or to compare them with Western medicine Many inhabitants of Ceylon have great faith in them, and there seems recently to have been a considerable increase in the number of patients seeking these forms of treatment The Indigenous Hospital in Colombo for example, has increased the number of outpatients attending per year by over 500% since 1942

The Ayurvedic system does not recognise surgical methods of treatment but many practitioners do not hesitate to prescribe and to dispense the latest synthetic drugs from the West Others have faith only in the ancient remedies, though all are handicapped by the difficulties of obtaining these in sufficiently large quantities and by the lack of an Ayurvedic pharmacopœia

These ancient arts cannot be ignored, indeed, where there are so few Western-trained practitioners, the indigenous systems may have to be supported and integrated into the over all system of medical care Some attempt to do this has been made in Ceylon There, in 1928, a Board of Indigenous Medicine was established by the government for the purpose of controlling and developing the local systems of medicine To date about 5000 applications for registration have been made A College of Indigenous Medicine, a hospital, a pharmacy, and a dispensary are also now maintained as government institutions Many local authorities and organisations have also established and financed Ayurvedic dispensaries It is the eventual hope to combine the best in all systems—to mix the East with the West It is an ambitious ideal that should not be confined solely to the arts of medicine

Fraud by Practitioner

It is not often that a National Health Service tribunal makes such findings of deliberate fraud on the part of a medical practitioner as were pronounced in the case of Dr M on the representation of the *London Executive Council* As the result of its inquiry the tribunal directed that his name be removed from the council's medical list and not included in any corresponding list kept by other councils and it ordered him to pay the costs of the hearing *The Minister of Health* has subsequently dismissed Dr M's appeal and has forbidden the inclusion of his name in any medical list till the tribunal or the Minister otherwise directs

The findings of the tribunal may be summarised as follows

In May, 1945 Dr M applied to be included in the council's medical list of practitioners undertaking to provide general

THE SLOUGH EXPERIMENT

A Comprehensive Industrial Health Service on Trial

THOSE not engaged in industrial medicine are apt to think of industry as conducted in large well-lit factories, equipped with specially designed machinery and echoing to the strains of *Music While You Work.* In fact, however, a good deal of industry is done with home-made equipment in small factories, some of which are cramped and dirty, having a random, back-kitchen sort of air. Into such unsuitable quarters a new process may be introduced which gives rise to potentially dangerous fumes or dust; and indeed even a large modern factory may develop unrecognised hazards when a new process is introduced. It is not at all easy to assess the degree of risk to health in such cases. An industrial doctor can give an opinion; and with some hazards he can measure by physiological methods the effects on individual workers, once these have developed; but what he really needs, in order to prevent illness, are means of measuring the concentration of toxic or dangerous substances at various places in the factory, and reliable standards of safety against which to check them. American practice is far ahead of us in this matter, as Dr. Peter Nash has pointed out in our columns.[1]

In America many States have set up divisions of industrial hygiene, usually as branches of their public-health departments. When a hazard is suspected the industrial hygiene laboratory examines air samples taken from various points in the factory, and supplies quantitative evidence of contamination. Moreover, the laboratory is staffed not only with doctors and chemists, but with engineers trained in industrial hygiene, whose task it is to recommend protective devices and to make sure that they are effective when installed.

We have no such pattern over here; but the Slough Industrial Health Service has established a pioneer occupational hygiene unit which is demonstrating what can, and should, be done.

THE OCCUPATIONAL HYGIENE TEAM

This service was founded in 1947, with the help of the Nuffield Foundation and the Nuffield Provincial Hospitals Trust, which between them granted £30,000 towards equipment and running expenses during the first five years. The aim was to promote the health and welfare of workers in local industry; and local firms were invited to become members of the service, paying a per-caput subscription (14s. at the outset, now 16s.) for their employees. Initially, 52 firms, employing 6324 workers, joined; and in five years these numbers have risen to 143 firms, with 15,175 employees. There are some 300 firms in the area, and though some of those not belonging to the service offer their own industrial health care, most of them do not provide for the care of their employees while at work. The service has thus still much opportunity to grow.

The occupational hygiene team was set up only three years ago. At the head of it is Dr. Nash, quoted above, who trained at the Harvard School of Public Health under Prof. Philip Drinker. He is assisted by Mr. R. J. Sherwood, an engineer, who has also trained in industrial hygiene under Professor Drinker, the Nuffield Foundation having sent him to Harvard for the purpose, and Miss Joan Bedford, a chemist, who has been provided with a laboratory in the London School of Hygiene and Tropical Medicine. All three members of the team hold joint appointments in the school and the Slough Industrial Health Service. They help to train students for the diploma in public health of London University, with which they thus provide a close bond.

[1] *Lancet,* 1952, ii, 478.

for special needs. Food in its natural state was the proper food for mankind. But in civilised conditions the food of city-dwellers had to be processed and preserved. They had to see to it that none of these processes or preservatives caused illness. He had great faith in the Ministry of Health and in the Medical Research Council who, he believed, kept all the necessary factors in view. He was not unduly alarmed by some things that had been said in the debate. He agreed with Lord Horder that it was dangerous to correlate these things without full information. It was true that certain cardiac diseases had increased, but the health of the people of this country had enormously improved since the 1920s. They should beware of too easy generalisations in this matter and not reach conclusions until the subject had been thoroughly investigated. The proper people to investigate it were disinterested people able to put forward the facts and to act upon them. Two things were important: the wartime policy should be continued and foods of special nutritive value should be made available to the poorest persons; and we should produce more of our own fresh food. In a world of great uncertainty, in peace or in war, we were still importing more than half the food we ate. He suggested that an attempt should be made to set the target at 75% healthy home-produced foods instead of only 60% above the pre-war figure by 1956.

Lord JESSEL pointed out the importance of matured flour in producing a stable dough which would make a good loaf under predetermined conditions. It was commercially impracticable for millers and bakers to provide the enormous storage facilities needed for maturing all the flour consumed in this country, and it was for this reason that improvers, which achieved the same results as storage in regard to the baking qualities and colour of the flour, were introduced. From all he had read, he could see no evidence that bread made from agenised flour had had any harmful effect on human beings; but he felt sure that the milling industry was more than willing to follow official recommendations as to what types of improvers they should use.

Lord SEMPILL urged the acceptance of Sir Edward Mellanby's advice that "no use of chemicals should be countenanced if they have harmful effects on animals," as agene had been shown to have.

THE GOVERNMENT REPLY

Lord CARRINGTON, replying for the Government, said there was every prospect that the Government's aim to increase production of food to 60% above the pre-war level by 1956 would be achieved. We must continue to rely on imports for a large part of our food-supply, and these were preserved or processed by methods which had little or no effect on the nutritive value of the food. As regards improvers in breadmaking, the Government had no intention of belittling or ignoring the evidence of the effect of agene on animals, or the other medical evidence which had been mentioned in the debate. It had been decided to abandon agene as soon as a suitable substitute could be found. They did not think, however, that the evidence so far available justified them in preventing the use of agene without knowing what would be the probable effects of the several substitutes which could be used. The only evidence the Ministry of Food had of any ill effects was the one case referred to in *The Lancet* last March. He would like to emphasise that in the 30 years during which agene had been widely used in this country this was really the only authenticated case of human allergy associated with agene or chlorine dioxide. He did not think this case should be considered a cause for alarm, and the Government did not intend to allow it to force them to take precipitate action. That point was also made in *The Lancet's* leading article. Investigations were now proceeding into the various alternatives to agene, conducted by the Ministries of Food and Health and the Medical Research Council, in collaboration with the research associations of the milling and baking industries. These investigations were designed to assess the relative suitability of the various improvers which included agene, chlorine dioxide, vitamin C, and a recently developed aeration process in which improvement was effected by high-speed mixing. The investigations included studies of any chemical changes produced in the flour's constituents, the effects on the health and growth of experimental animals of feeding them with the treated flours, and assessment of the quality of the breads made from treated flours. They also included both small-scale and commercial trials of the vitamin C and aeration processes. The work was being pushed on as fast as possible, but there were difficult problems involved, and, if they were to be adequately examined, a quick answer could not be expected. The Government had in mind the need to ensure a supply of bread which would meet the nutritional needs of the nation. Lord Carrington said he felt there was no need for additional inquiry into the matter. He was inclined to be cautious of the words "artificial" and "poisonous" which had been used in the debate. Poisonous was a dramatic word, but it could be misleading. The addition of some chemicals was necessary if 50 million people were to be fed in this country and, with safeguards, there was no cause for disquiet.

Lord TEVIOT's motion was withdrawn, and Lord HANKEY said that although he was not entirely satisfied, he would not move his motion that day.

Medical Services in the Gas Industry

In the House of Commons on June 9, Mr STEPHEN SWINGLER said that the Gas Council, almost alone today among national boards and national councils of industries, had not established on a national scale an industrial medical service for their workers, yet the gas industry had special medical problems and the Medical Research Council had recently decided to undertake long-term research into the incidence of lung cancer among gas-workers. It was, therefore, disappointing to find that only 4 out of the 12 area boards in the gas industry had full-time medical staffs. Mr Swingler believed that the Minister of Fuel and Power was not entirely convinced that the present medical arrangements in the industry were satisfactory, and he hoped that if the Minister could not persuade the council to establish an occupational health service he would use his powers of direction under the Act.

Dr BARNETT STROSS suggested that if the Government held it desirable to have a comprehensive health service for the country as a whole, it should start with those industries where the risks of accident or occupational disease were greatest. It was unlikely that the Medical Research Council would complete their investigation into the incidence of lung cancer among gas-workers under two or three years, and the Ministry should urge that the service given to gas-workers should at least be evened up to the best level in any area in the country.

Mr L. W. JOYNSON-HICKS, parliamentary secretary to the Ministry of Fuel and Power, feared that there was no hope of getting results from the M.R.C. investigations even in two or three years, but he did not think that the fact that there were only 4 permanent medical officers of the boards had any effect on this issue. Turning to the points raised by Mr Swingler, he said that it was not the job of the Gas Council to set up a medical service for the industry. That was a matter for each area board to do for itself in the light of their local experience. When the industry was nationalised the Government of the day appointed a committee on industrial health services—the Dale Committee—and shortly afterwards development in industrial medical services was held up pending the committee's report. Early in 1951 the ban was removed and the committee's recommendations were referred to the National Joint Advisory Council. Replies had now been received from the British Employers' Federation and from each of the nationalised industries, but no reply had yet been received from the T.U.C. Consequently, action on these recommendations could not be taken. In the meantime, the Ministry were determined to progress. Some of the area boards were reluctant, or had been so in the past, for many good reasons. One was the question of expense, for to set up these medical services was costly. Moreover, the boards had been heavily occupied in general reorganisation. The Minister did not think that there was a case here for direction. If there was to be a successful permanent medical service, When a request comes from a firm for the investigation of a suspected hazard—say from fumes or dust—Dr. Nash first looks over the factory and examines those likely to have been affected, sending physiological samples for examination, or arranging radiography or blood-counts as necessary. Mr. Sherwood then visits the factory, takes samples of air at likely danger-points, and examines existing protective devices. All the medical and engineering findings are combined into a report which notes any damage to health and sets the quantitative results of air analyses against the proportion of a particular contaminant considered dangerous by the Medical Research Council and by American authorities. If the proportion of contaminant has proved to be too high for safety, the report concludes with some clear proposals for improving matters—usually by arranging for better exhaust ventilation, or other protective devices; photographs and illustrations are included if necessary. Neatly bound copies of the report are sent to the firm, and as a result the necessary changes are usually made.

The annual report of the Slough Industrial Service for 1951–52 notes that in a study made for one firm, which casts a lead-antimony alloy, no lead hazard was discovered but undesirable concentrations of antimony were present. Recommendations were made for preventing this. In another factory a risk from asbestos dust has been removed by local exhaust ventilation, installed on the team's advice; the workers here were all examined radiographically. Ten reports were made to firms using toxic substances, and advice for improving conditions given to 6. An outbreak of dermatitis among packers exposed to liquid paraffin has been brought to an end; and the medical officer of health of a large London borough has been assured that a chromium-plating factory, about which local residents were complaining, is doing no harm.

The work of the team, in their first three years, has grown so fast that they are unable to cope with all the requests reaching them. These include invitations to examine the dust hazards for workers in the whole of the diamond cutting and polishing industry, and in a large grinding-wheel and abrasives factory. In fact this pioneer unit, the only one of its kind in the country, has demonstrated conclusively the need for others—perhaps a dozen scattered up and down the United Kingdom, like the public-health laboratories.

THE ROUTINE SERVICE

The occupational hygiene team, however, is doing only a relatively small—though highly important—part of the work of the service as a whole. Under the medical direction of Dr. A. Austin Eagger, the service provides casualty care for workers from all the member firms, industrial nursing, physiotherapy, remedial gymnastics, social services, and recuperative treatment in a residential centre at Farnham Park nearby.

The central clinic is quartered in a solid square building, part of the Slough Community Centre. It contains, besides a large casualty department, rooms where clean dressings are done (no-touch technique is used), a room for the trained social worker, a chiropodist's surgery, administrative and record rooms, consulting-rooms where members of the staff of the Canadian Red Cross Memorial Hospital hold outpatient sessions, and an X-ray department shared by these hospitals, and of course by the clinic. This liaison with the local hospitals and their consultants has been of the greatest value. It means that a difficult or serious case can—with the consent of the general practitioner—be seen on the spot by an appropriate specialist, and if necessary the patient can be admitted to one of his hospital beds. Continuity of treatment is thus the rule rather than the exception, and this appeals to the patient as much as the doctor. Moreover the arrangement is doing much to win the confidence of local general practitioners who at the outset were somewhat suspicious of the service. Most of them are now on good terms with Dr. Eagger and his staff, and refer cases to the centre on their own initiative, well aware that in this way they can count on getting a consultant's opinion at once when necessary. Two orthopædic clinics are held weekly, and the consultant orthopædic surgeon of the area is also a paid member of the clinic staff. The X-ray department examines some 14 cases a day—mostly bone injuries, but also some cases of suspected tuberculosis or other chest conditions.

MINOR INJURIES

The clinic staff deal with about 3 serious accidents a month, most of which require hospital care; but their major concern is with minor accidents, of which some 500 daily come their way. Such things as foreign bodies or splashes in the eye, and damaged fingers or hands respond quickly to effective treatment at the outset. Neglected, they may mean great discomfort as well as loss of time. The finger which has gone septic can keep a man anchored to the hospital casualty department for many hours a day. At Slough he can be treated first at the centre, and afterwards by the team of the mobile dressing-station which travels round the member firms every morning for this very purpose. The patient leaves his job when the van arrives, and may be back at work in ten minutes. The mobile dressing-station is staffed by a State-registered nurse, who does the dressings, and a doctor who pays routine visits, in the afternoons, to examine personnel at the various factories. There is also an accident van with an emergency team of doctor and nurse, which goes to the scene of an accident as soon as a call comes in to the centre. Seriously injured patients are brought in by ambulance; and thanks to the close liaison between the centre and the Emergency Bed Service it is always possible to get a bed for anyone who needs it.

The records of minor accidents kept at the centre are of a time-saving pattern, but very full and informative. An average of 50 eye injuries—mostly due to foreign bodies or splashes—are seen weekly. More than once it has been possible to point out to a firm that they are getting a high incidence of accidents of a certain type, and that these are preventable; with the result that the firms have asked the occupational hygiene team for advice on ways of preventing them.

Each firm, of course, has its own first-aid team, manned by volunteers. At one time volunteers were hard to find, because time spent in learning first-aid reduced the bonus for the group in which the volunteer worked. The firms were asked to adjust this difficulty, and did so; and as a result volunteers have come forward to take the course of training organised by the service. The standard of first-aid has risen rapidly, and now these lay helpers are able to deal with 60% of minor casualties. These various arrangements, it is estimated, save 2000 man-hours a month.

ANCILLARY SERVICES

It often happens that a patient recovering from an injury, or suffering from a rheumatic or other affection of the joints or muscles, needs remedial exercises or physiotherapy; but to get this at hospital he may have to spend hours away from work. The physiotherapy department of the centre is housed in an adjoining building, and is very active. Patients come by appointment, and are away from their work only for as long as their treatment requires. The community centre swimming-bath can be used by those who need to do water-borne exercises. The chiropodist employed by the centre holds two sessions a week.

RECUPERATION AT FARNHAM PARK

A well-run and very agreeable course of reablement is offered at Farnham Park to those patients who need it. They go either as residents or outpatients to this fine house with wide gardens, where they work hard at recovery every day until 4·30 P.M. They may be sent either to the workshops, where there are plenty of ingenidrifting back towards "poverty bread." As though more than 200 years of "improving" flour, first by the addition of alum and other whiteners and later by the abstraction of the essentials of health, were not enough, in 1921 agene was introduced so surreptitiously that it was not even mentioned in the first edition of *The Englishman's Food*, and Lord Hankey, who was watching these things closely because he was horrified by the fact that 60% of our would-be recruits for the Army were being rejected, had never heard of agene until 1946 when Sir Edward Mellanby showed that agenised flour produced nervous disorders in dogs and, if continued, canine hysteria and eventually death. In 1950, after the usual haggling between the trade and the scientists, the Government at last decided to ban agene but to permit chlorine dioxide which they said it would take a long time to provide. So long had it taken that seven years after Mellanby's warning the banned and discredited agene was still in general use and chlorine dioxide was suspect.

In support of the technical case against agene, Lord Hankey referred to the experiments in 1940 by Dr. Coghlan, of Hull, Dr. Pollak, the physician in charge of the allergy clinic at the Middlesex Hospital, and the paper by Dr. Sheldon and Dr. Yorke published in *The Lancet* on March 21, 1953. To the layman Dr. Coghlan's letter to the *Medical Press* on April 2, 1952, provided presumptive evidence of a tendency for agene to induce coronary thrombosis and other diseases of the heart and circulatory system and also suggested that certain reactions set up ideal conditions for ulcer formation. This disturbing indictment was supported by official statistics. But heart and vascular diseases were not the only complaints in respect of which agenised flour was suspect. Dr. Pollak, in a report to the *Medical Press* in July, 1950, showed that there were many people who, while tolerant of flour made from the wheat berry, had allergic symptoms on eating bread made from agenised flour. The experiments of Dr. Sheldon and Dr. Yorke led to the unescapable conclusion that chemically treated flour was the cause of serious skin disorders associated with loss of appetite and mental depression. Agene was the original cause of the trouble but chlorine dioxide was found to produce the same symptoms.

Summarising the case against agene, Lord Hankey said that there was no dispute that it was injurious to dogs and some other animals. Secondly, many of the nations which consumed mainly white bread had prohibited agene, and France, which did not permit its use, seemed, prima facie, to have suffered much less severely than we had from some of the more serious diseases which agene was suspected of promoting. Thirdly experts had warned us that agene might promote tendencies towards coronary thrombosis and other heart and vascular diseases, ulcers, skin diseases, and lack of appetite, and the list in Dr. Franklin Bicknell's book, *The English Complaint*, was even longer. But he did not claim that the case against agene as he had presented it provided proof, as a whole or in part, that agene was deleterious. Here Lord CARRINGTON, parliamentary secretary to the Ministry of Agriculture, interjected: Neither does *The Lancet*. Lord Hankey said that was perfectly true, but there were a great many other things in the leading article in *The Lancet* which he dare say he could quote. The governments of the United States and Canada had found the evidence sufficient to justify their banning agene, and no one had been able to prove that agene was not as dangerous as the "poverty bread" to the teeth of the nation. If he were responsible for the decision, he would want to be convinced of some overwhelming health advantage in agene before he permitted its continuance for a single day.

Turning to the supposed advantages of agene, Lord Hankey recalled that, in 1951, Major Lloyd George, Minister of Food, said:

> Flour treated with agene yields a dough which has more uniform baking qualities and is more easily handled by the baker; the resulting loaf is whiter and of superior lightness and texture. Agene treatment has no effect on the keeping quality of the flour.

But Lord Hankey thought that the implication that agene was necessary to obtain these qualities was illusory. In France, where agene was banned, the bread had all these qualities, and was much more palatable than ours. It could not be said that the health of the consumer had been considered first in this matter; the only people who got any benefit were possibly the millers and certainly the "other interests" who supplied the unnecessary agene and the other chemical improvers and emulsifiers.

Lord HORDER said that last year, when this matter was under debate, he had drawn attention to the frequency with which that very common fallacy of non sequitur seemed to arise in this matter. For example, Lord Teviot had mentioned cancer. With what causative agent could they associate the incidence of that disease? They would be only too pleased to get that information. Again, Lord Hankey had asked, if the increase in the incidence of coronary thrombosis was not due to agene what was it due to? He wished he knew. These statements really did require checking. In New Zealand agene had never been used in the preparation of bread, and the incidence of coronary thrombosis in New Zealand was exactly comparable with its incidence in this country. To quote part of what *The Lancet* said and not all was not quite fair. The purpose of improvers in flour was to make the bread acceptable to the senses—to the palate, to the eye, and to the smell—as well as nutritious. There were two very simple desiderata: bread, being the staple article of diet of 50 million people in the islands, must be nutritious up to the limit of scientific knowledge of nutrition today, and it was a Governmental responsibility to see that it was. Next autumn cereals were to be decontrolled and he shared the anxiety which had been expressed as to whether the Government were going to see that the minimum of nutritional ingredients were preserved in the whiter loaf. He understood that was their intention. He strongly opposed the introduction, even the availability, of this whiter bread unless that safeguard was assured.

Agene was given up by America rather more than two years ago and there coronary thrombosis had increased still further during that period. He was not one of those who had been convinced that agene had produced any illness in human beings. He knew of no series of nervous complaints which even suggested that they were produced by the same reagent as in the case of canine hysteria produced by agene. Both the doctors who reported the case of the lady with the peculiar skin in *The Lancet* were fair enough to raise the question whether this was a rare, an isolated, case or whether it was opening up a new field on the nervous side of disease—something that had not been met before. Lord Hankey preferred the second conclusion because it fitted his thesis, but Lord Horder said that he, with no less knowledge, chose the first. He thought the Government were justified in going on with agene until an improver could be introduced which cut out the chemical altogether. We should not hurry the change from one chemical to another as the Americans had done. The chemical improver to which they had switched was not known to be either better or worse than the original one. The bakers and the millers should work at this problem and, as soon as might be, change over from a chemical improver to a physical one.

Viscount BLEDISLOE said that about 30 years ago Lord Horder, as his medical adviser, had advised him not to take medicines unless absolutely necessary and to give Nature a chance. In carrying out Lord Horder's advice, we should also give the products of Nature a chance without undue adulteration. There should be an impartial investigation into this problem so that both the medical profession and the Government could speak with greater assurance on the subject than they could today.

Lord BOYD-ORR said that nutrition was by far the most important factor in health. A great improvement had been achieved in the health of the women and children of this country today compared with the pre-war years. It was interesting and important to note that that improvement was made during the war amid a food shortage and when the enemy was at our gates. The Government of that time ensured proper food priorities ous devices to keep particular muscle-groups exercised, or to the warm plunge-bath, where physiotherapists exhort and persuade the gaily clad bathers to achieve the next stage of activity, or to the gymnasium, where the instructor notes with pride the gain in power of limbs impaired by poliomyelitis or other disorder. From 4·30 to 9.30 P.M. the patients are off duty. They can have tea in the handsome lounge, rest and read in the quiet room, chat or play games in the common-room, walk in the grounds, go out and visit friends, or join in the programme arranged by their own entertainments committee. On three evenings a week the education and recreation department provides programmes of documentary and instructional films, or arranges discussions, games, or plays by local amateur dramatic societies or by the patients themselves. All the patients have physical disabilities. Treatment for industrial patients with neuroses is, of course, available at Roffey Park, near Horsham. The average stay at Farnham Park is four weeks—the longest ten weeks. The food is very good, and so is the morale of the patients; perhaps the two are linked.

The Slough Industrial Health Service is thus a comprehensive scheme for the welfare of workers in industry, and has already shown its member firms a good return in the saving of working-time. The workers themselves at first regarded it with the customary scepticism of the British working man, who is always wary of institutions outspokenly designed to do him good. Gradually, however, they have come to recognise the value of the service, and now make full use of it.

SCURVY

The Edinburgh Meeting

As already recorded in these pages, the Royal College of Physicians of Edinburgh and the Nutrition Society combined during the weekend of May 22 to celebrate in Edinburgh the bicentenary of the publication of Lind's *Treatise of the Scurvy*.[1]

The proceedings opened with a "special graduation ceremonial" at which the Vice-Chancellor (Sir Edward Appleton, F.R.S.) conferred the honorary degree of doctor of laws upon Surgeon Vice-Admiral Sir **Sheldon Dudley**, F.R.S. In a fighting speech Sir Sheldon said that the medical officer in the Royal Navy must educate his executive superior in practical hygiene, and that the importance of this subject was so great that there should be a health officer on the Board of Admiralty. There was, he declared, no such entity as subclinical scurvy, and he believed that less than 15 mg. daily of ascorbic acid was a maintenance dose although during the war dietitians had tried to persuade him that the figure was 300 mg. At the conclusion of the ceremony a bronze plaque commemorating Lind was unveiled, the gift of the Sunkist Growers of Citrus Fruit in California and Arizona. Later in the day another formal speech was made—this time by Prof. V. P. **Sydenstricker** (Augusta, Georgia), who gave the Sydney Watson Smith lecture in the Royal College of Physicians on the Impact of Vitamin Research on the Practice of Medicine.

* * *

The scientific meetings of the Nutrition Society were opened by Sir **Edward Mellanby**, F.R.S., who stated that Lind was the first to introduce the experimental method into medicine. He cruised in safer waters when he came to contemporary history and reminded us of the service Sir Sheldon Dudley had performed in establishing the Royal Naval Personnel Research Committee, and of the careful researches on nutrition of Dame Harriette Chick over many years; he and she were the only two surviving members of the original Accessory Food Factors Committee set up jointly in 1917 by the Medical Research Committee and the Lister Institute. Dame **Harriette Chick** then reviewed the early investigations of scurvy and incidentally differed from Sir Sheldon in affirming the existence of the prescorbutic state. Later in the symposium a paper on authors on scurvy before Lind was read on behalf of Mr. A. J. **Lorenz**.

Perhaps the most important contribution of the session was given by Mr. C. G. **King**, PH.D. (Nutrition Foundation, New York City), who by labelling compounds with ^{14}C has indicated how L-ascorbic acid is formed in the body of the rat from D-glucose, D-glucuronic acid being an intermediate. He has also made the interesting observation that with deficiency of ascorbic acid there is an increased formation of cholesterol from acetate; but, although he is a champion of high human allowances of ascorbic acid, he was careful not to claim that ingestion of the vitamin would decrease atherosclerosis.

This relation to cholesterol metabolism is possibly related to one of the most interesting aspects of ascorbic acid, its connection with the adrenal cortex. Ascorbic acid may form as much as 4% of the dry weight of the adrenal cortex, and the vitamin was of course initially isolated from adrenals by Szent-Györgyi in 1927. Sayers[2] and his colleagues have shown that adrenal ascorbate is reduced by corticotrophin (A.C.T.H.) or by various stresses. It is possible that an oxidation product of ascorbic acid is required for the synthesis of adrenal cortical hormone from cholesterol, and it may be that corticotrophin promotes the oxidation of ascorbic acid; Cornforth and Long[3] have suggested that cortisone promotes the peripheral oxidation of ascorbic acid.

Prof. R. M. **Kark** (Chicago) reviewed the relation of ascorbic acid to scurvy, corticotrophin, and surgery: he claimed that there was no evidence that cold or adrenal cortical activity increases the human requirement of ascorbic acid, and he did not believe that ascorbic acid or a derivative of it is used in synthesising adrenal hormones.

The Lind tradition of experimental work on man was upheld by papers from Dr. J. H. **Crandon** (Boston) and Prof. H. A. **Krebs**, F.R.S. Dr. Crandon described the now classical experiment[4] in which he subsisted for six months on a diet containing no vitamin C; subsequently he has investigated the relation of ascorbic acid to surgery. Professor Krebs described the similar experiment later conducted in Sheffield on conscientious objectors.[5] In the latter experiment a supplement of 10 mg. of ascorbic acid daily was found to cure clinical scurvy in all six volunteers and protected three volunteers from scurvy for 424 days; this figure of 10 mg. was somewhat arbitrarily trebled to arrive at a figure which would satisfy "ill-defined additional needs and to allow a margin of safety." Even this figure of 30 mg. is of course very much lower than that required for saturation: in a delightful paper Prof. **Gounelle**, of Paris, informed the meeting that he had found that tuberculous prisoners-of-war did not become saturated until they were given 300 mg. daily. The question whether saturation is desirable or necessary was taken up by Dr. King in the discussion at the end of the sessions when he defended the daily allowance of 75 mg. of ascorbic acid recommended by the National Research Council. Mr. L. J. **Harris**, SC.D., had suggested that the question of requirement was one that needed discussion, and, after pronouncing himself in favour of saturation, he called on Dr. King. Dr. **King** said that 75 mg. gave only half-saturation; the guineapig allowed to choose its diet kept itself saturated, and animals that synthesised their own ascorbic acid were saturated; it could be shown that guineapigs survived diphtheria toxin better on high levels (5–10 mg. daily) than on lower levels (2–5 mg.), even though these lower levels completely protected for special needs Food in its natural state was the proper food for mankind But in civilised conditions the food of city-dwellers had to be processed and preserved They had to see to it that none of these processes or preservatives caused illness He had great faith in the Ministry of Health and in the Medical Research Council who, he believed kept all the necessary factors in view He was not unduly alarmed by some things that had been said in the debate He agreed with Lord Horder that it was dangerous to correlate these things without full information It was true that certain cardiac diseases had increased but the health of the people of this country had enormously improved since the 1920s They should beware of too easy generalisations in this matter and not reach conclusions until the subject had been thoroughly investigated The proper people to investigate it were disinterested people able to put forward the facts and to act upon them Two things were important the wartime policy should be continued and foods of special nutritive value should be made available to the poorest persons . and we should produce more of our own fresh food In a world of great uncertainty in peace or in war, we were still importing more than half the food we ate He suggested that an attempt should be made to set the target at 75% healthy home-produced foods instead of only 60% above the pre-war figure by 1956

[5] *Lancet*, 1948, i, 853.

Lord **JESSEL** pointed out the importance of matured flour in producing a stable dough which would make a good loaf under predetermined conditions It was commercially impracticable for millers and bakers to provide the enormous storage facilities needed for maturing all the flour consumed in this country, and it was for this reason that improvers, which achieved the same results as storage in regard to the baking qualities and colour of the flour, were introduced From all he had read, he could see no evidence that bread made from agenised flour had had any harmful effect on human beings; but he felt sure that the milling industry was more than willing to follow official recommendations as to what types of improvers they should use

Lord **SEMPILL** urged the acceptance of Sir Edward Mellanby's advice that "no use of chemicals should be countenanced if they have harmful effects on animals,' as agene had been shown to have

THE GOVERNMENT REPLY

Lord **CARRINGTON**, replying for the Government said there was every prospect that the Government's aim to increase production of food to 60% above the pre-war level by 1956 would be achieved We must continue to rely on imports for a large part of our food-supply, and these were preserved or processed by methods which had little or no effect on the nutritive value of the food As regards improvers in breadmaking the Government had no intention of belittling or ignoring the evidence of the effect of agene on animals or the other medical evidence which had been mentioned in the debate It had been decided to abandon agene as soon as a suitable substitute could be found. They did not think, however, that the evidence so far available justified them in preventing the use of agene without knowing what would be the probable effects of the several substitutes which could be used The only evidence the Ministry of Food had of any ill effects was the one case referred to in *The Lancet* last March He would like to emphasise that in the 30 years during which agene had been widely used in this country this was really the only authenticated case of human allergy associated with agene or chlorine dioxide He did not think this case should be considered a cause for alarm, and the Government did not intend to allow it to force them to take precipitate action. That point was also made in *The Lancet*'s leading article Investigations were now proceeding into the various alternatives to agene, conducted by the Ministries of Food and Health and the Medical Research Council, in collaboration with the research associations of the milling and baking industries These investigations were designed to assess the relative suitability of the various improvers which included agene chlorine dioxide, vitamin C, and a recently developed aeration process in which improvement was effected by high-speed mixing The investigations included studies of any chemical changes produced in the flour's constituents the effects on the health and growth of experimental animals of feeding them with the treated flours, and assessment of the quality of the breads made from treated flours They also included both small-scale and commercial trials of the vitamin C and aeration processes The work was being pushed on as fast as possible but there were difficult problems involved, and, if they were to be adequately examined a quick answer could not be expected The Government had in mind the need to ensure a supply of bread which would meet the nutritional needs of the nation Lord Carrington said he felt there was no need for additional inquiry into the matter He was inclined to be cautious of the words "artificial" and "poisonous" which had been used in the debate. Poisonous was a dramatic word but it could be misleading The addition of some chemicals was necessary if 50 million people were to be fed in this country: and, with safeguards, there was no cause for disquiet

Lord **TEVIOT**'s motion was withdrawn, and Lord **HANKEY** said that although he was not entirely satisfied, he would not move his motion that day

Medical Services in the Gas Industry

In the House of Commons on June 9, Mr **STEPHEN SWINGLER** said that the Gas Council almost alone today among national boards and national councils of industries, had not established on a national scale an industrial medical service for their workers, yet the gas industry had special medical problems and the Medical Research Council had recently decided to undertake long-term research into the incidence of lung cancer among gas-workers It was, therefore disappointing to find that only 4 out of the 12 area boards in the gas industry had full-time medical staffs Mr Swingler believed that the Minister of Fuel and Power was not entirely convinced that the present medical arrangements in the industry were satisfactory, and he hoped that if the Minister could not persuade the council to establish an occupational health service he would use his powers of direction under the Act.

Dr **BARNETT STROSS** suggested that if the Government held it desirable to have a comprehensive health service for the country as a whole it should start with those industries where the risks of accident or occupational disease were greatest It was unlikely that the Medical Research Council would complete their investigation into the incidence of lung cancer among gas-workers under two or three years and the Ministry should urge that the service given to gas-workers should at least be evened up to the best level in any area in the country

Mr **L W. JOYNSON-HICKS**, parliamentary secretary to the Ministry of Fuel and Power, feared that there was no hope of getting results from the M R C investigations even in two or three years, but he did not think that the fact that there were only 4 permanent medical officers of the boards had any effect on this issue Turning to the points raised by Mr Swingler, he said that it was not the job of the Gas Council to set up a medical service for the industry That was a matter for each area board to do for itself in the light of their local experience When the industry was nationalised the Government of the day appointed a committee on industrial health services—the Dale Committee—and shortly afterwards development in industrial medical services was held up pending the committee's report. Early in 1951 the ban was removed and the committee's recommendations were referred to the National Joint Advisory Council Replies had now been received from the British Employers' Federation and from each of the nationalised industries but no reply had yet been received from the T U C Consequently action on these recommendations could not be taken. In the meantime the Ministry were determined to progress Some of the area boards were reluctant, or had been so in the past. for many good reasons One was the question of expense for to set up these medical services was costly Moreover the boards had been heavily occupied in general reorganisation The Minister did not think that there was a case here for direction. If there was to be a successful permanent medical service

When a request comes from a firm for the investigation of a suspected hazard—say from fumes or dust—Dr. Nash first looks over the factory and examines those likely to have been affected, sending physiological samples for examination, or arranging radiography or blood-counts as necessary. Mr. Sherwood then visits the factory, takes samples of air at likely danger-points, and examines existing protective devices. All the medical and engineering findings are combined into a report which notes any damage to health and sets the quantitative results of air analyses against the proportion of a particular contaminant considered dangerous by the Medical Research Council and by American authorities. If the proportion of contaminant has proved to be too high for safety, the report concludes with some clear proposals for improving matters—usually by arranging for better exhaust ventilation, or other protective devices; photographs and illustrations are included if necessary. Neatly bound copies of the report are sent to the firm, and as a result the necessary changes are usually made.

The annual report of the Slough Industrial Service for 1951–52 notes that in a study made for one firm, which casts a lead-antimony alloy, no lead hazard was discovered but undesirable concentrations of antimony were present. Recommendations were made for preventing this. In another factory a risk from asbestos dust has been removed by local exhaust ventilation, installed on the team's advice; the workers here were all examined radiographically. Ten reports were made to firms using toxic substances, and advice for improving conditions given to 6. An outbreak of dermatitis among packers exposed to liquid paraffin has been brought to an end; and the medical officer of health of a large London borough has been assured that a chromium-plating factory, about which local residents were complaining, is doing no harm.

The work of the team, in their first three years, has grown so fast that they are unable to cope with all the requests reaching them. These include invitations to examine the dust hazards for workers in the whole of the diamond cutting and polishing industry, and in a large grinding-wheel and abrasives factory. In fact this pioneer unit, the only one of its kind in the country, has demonstrated conclusively the need for others—perhaps a dozen scattered up and down the United Kingdom, like the public-health laboratories.

THE ROUTINE SERVICE

The occupational hygiene team, however, is doing only a relatively small—though highly important—part of the work of the service as a whole. Under the medical direction of Dr. A. Austin Eagger, the service provides casualty care for workers from all the member firms, industrial nursing, physiotherapy, remedial gymnastics, social services, and recuperative treatment in a residential centre at Farnham Park nearby.

The central clinic is quartered in a solid square building, part of the Slough Community Centre. It contains, besides a large casualty department, rooms where clean dressings are done (no-touch technique is used), a room for the trained social worker, a chiropodist's surgery, administrative and record rooms, consulting-rooms where members of the staff of the Canadian Red Cross Memorial Hospital hold outpatient sessions, and an X-ray department shared by these hospitals, and of course by the clinic. This liaison with the local hospitals and their consultants has been of the greatest value. It means that a difficult or serious case can—with the consent of the general practitioner—be seen on the spot by an appropriate specialist, and if necessary the patient can be admitted to one of his hospital beds. Continuity of treatment is thus the rule rather than the exception, and this appeals to the patient as much as the doctor. Moreover the arrangement is doing much to win the confidence of local general practitioners who at the outset were somewhat suspicious of the service. Most of them are now on good terms with Dr. Eagger and his staff, and refer cases to the centre on their own initiative, well aware that in this way they can count on getting a consultant's opinion at once when necessary. Two orthopædic clinics are held weekly, and the consultant orthopædic surgeon of the area is also a paid member of the clinic staff. The X-ray department examines some 14 cases a day—mostly bone injuries, but also some cases of suspected tuberculosis or other chest conditions.

MINOR INJURIES

The clinic staff deal with about 3 serious accidents a month, most of which require hospital care; but their major concern is with minor accidents, of which some 500 daily come their way. Such things as foreign bodies or splashes in the eye, and damaged fingers or hands respond quickly to effective treatment at the outset. Neglected, they may mean great discomfort as well as loss of time. The finger which has gone septic can keep a man anchored to the hospital casualty department for many hours a day. At Slough he can be treated first at the centre, and afterwards by the team of the mobile dressing-station which travels round the member firms every morning for this very purpose. The patient leaves his job when the van arrives, and may be back at work in ten minutes. The mobile dressing-station is staffed by a State-registered nurse, who does the dressings, and a doctor who pays routine visits, in the afternoons, to examine personnel at the various factories. There is also an accident van with an emergency team of doctor and nurse, which goes to the scene of an accident as soon as a call comes in to the centre. Seriously injured patients are brought in by ambulance; and thanks to the close liaison between the centre and the Emergency Bed Service it is always possible to get a bed for anyone who needs it.

The records of minor accidents kept at the centre are of a time-saving pattern, but very full and informative. An average of 50 eye injuries—mostly due to foreign bodies or splashes—are seen weekly. More than once it has been possible to point out to a firm that they are getting a high incidence of accidents of a certain type, and that these are preventable; with the result that the firms have asked the occupational hygiene team for advice on ways of preventing them.

Each firm, of course, has its own first-aid team, manned by volunteers. At one time volunteers were hard to find, because time spent in learning first-aid reduced the bonus for the group in which the volunteer worked. The firms were asked to adjust this difficulty, and did so; and as a result volunteers have come forward to take the course of training organised by the service. The standard of first-aid has risen rapidly, and now these lay helpers are able to deal with 60% of minor casualties. These various arrangements, it is estimated, save 2000 man-hours a month.

ANCILLARY SERVICES

It often happens that a patient recovering from an injury, or suffering from a rheumatic or other affection of the joints or muscles, needs remedial exercises or physiotherapy; but to get this at hospital he may have to spend hours away from work. The physiotherapy department of the centre is housed in an adjoining building, and is very active. Patients come by appointment, and are away from their work only for as long as their treatment requires. The community centre swimming-bath can be used by those who need to do water-borne exercises. The chiropodist employed by the centre holds two sessions a week.

RECUPERATION AT FARNHAM PARK

A well-run and very agreeable course of reablement is offered at Farnham Park to those patients who need it. They go either as residents or outpatients to this fine house with wide gardens, where they work hard at recovery every day until 4·30 P.M. They may be sent either to the workshops, where there are plenty of ingenithe Ministry must carry both sides of the industry with them Progress had been made The Scottish Board had agreed to a permanent medical service The Gas Council as a council had also agreed and their views were shared by the Minister But some of the boards were in a special category For instance Mr Joynson-Hicks did not think it would ever be the best thing for the Wales Gas Board to have a permanent medical service They had a different set-up and different problems The Northern Board also had different circumstances By and large, it was reasonable to expect that the remaining boards would be taking action, and therefore they had achieved a considerable step towards getting a permanent medical service for the gas industry He hoped it would not be long before that service was available

QUESTION TIME

The Guillebaud Inquiry

Replying to questions Mr J Stuart Secretary of State for Scotland said an experienced officer of the Department of Health for Scotland was being specially appointed to the secretariat of the committee of inquiry into the National Health Service to assist on matters specially affecting Scotland It was for the committee themselves to decide having regard to their terms of reference, the nature and scope of their review As to the question of the protection of the Scottish people in this matter, he understood that the committee had invited memoranda from Scottish bodies and intended to hear oral evidence in Scotland, so that they would become fully aware of the Scottish needs and circumstances He had no doubt they would have due regard to the Highlands and Islands

Mr Hector Hughes In view of the widespread alarm which the appointment of this committee has caused in Scotland could the Minister give an assurance that the advantages which the Scottish people have enjoyed for the last six years will be in no way imperilled ?

Mr Stuart I can only draw the attention of the hon Member to the terms of reference which end by saying ' while providing for the maintenance of an adequate service " That is our intention

B C G Vaccine in the Army

Replying to a question Mr A Head, Secretary of State for War, said that B C G vaccine was not under test but was already in use by the Army Members of the Royal Army Medical Corps and Queen Alexandra's Royal Army Nursing Corps who, on testing by the Mantoux technique appeared to be susceptible to tuberculosis were offered this form of vaccination and might not be employed in a tuberculosis ward or laboratory unless, following the treatment a further test gave a satisfactory reaction

Medical Examination of National Service Recruits

Replying to a question Sir Walter Monckton, Minister of Labour and National Service, said that the study undertaken by the London School of Hygiene and Tropical Medicine into the results of examinations of men called up for National Service was a statistical survey of some aspects of the medical conditions of a limited number of men The Ministry of National Service made available some data, but the inquiry was not made on their behalf nor had he any responsibility for its conclusions

Mr D L Donnelly asked whether it was not a fact that the inquiry had been widened and would not the Minister who had been approached by the London School of Hygiene and Tropical Medicine give full consideration to such an inquiry, as this was one of the rare occasions when full data of the nation's health could be collected

Sir Walter Monckton said this was a pilot inquiry and dealt with one medical board and one place only A wider inquiry was now thought necessary and if it went forward the Ministry of National Service would provide data as they had done before

Hospitals and the Bread Subsidy

Replying to a question Dr Charles Hill, parliamentary secretary to the Ministry of Food said the proposal to give a subsidy to hospitals in respect of bread which they baked for their own use had been considered but the Minister did not think that such a widening of bread subsidy payments would be justified

In England Now

A Running Commentary by Peripatetic Correspondents

If you accept the self-demand principle in infant feeding, you cannot make a diagnosis of "overfeeding" can you ? The infant's demand is your guide He may be underfed if he is not getting enough, but he cannot "overfeed" himself Here on the Pacific Coast the self-demand method is well-entrenched. The mothers like it The babies like it Early mixed feeding is the rule A baby of two months, amply breast-fed, will take daily half a banana, two ounces of 'Pablum,' and half a can of peach custard He may look pale and obese, but that is irrelevant If you are following the self-demand method, other standards—æsthetic or avoirdupois—do not apply

But what troubles me is this. when do you begin to diagnose obesity ? Ten million people in North America are said to suffer from it It afflicts children as well as adults A 12-year old schoolgirl weighs 200 lb If you didn't diagnose that as obesity, you would have to use some other term meaning the same thing But to put it crudely, obesity is usually due to overfeeding and when do you begin to diagnose overfeeding We have agreed that there is no such thing in infants And everybody knows (or should know) that you respect the dietary inclinations of the toddler Overfeeding of a toddler is just unthinkable Would you then concede obesity in the nursery school ? In the 5-year-old ? When does appetite cease to be a standard and begin to be a menace ? We shall have to make up our minds soon, because these self-demand-fed expansive infants will soon be turning up in the schools and will have to be put on a Wetzel grid

Dietary regimentation is going to be tough for these uninhibited youngsters "Not at all," you will hear some expert say, "Just the reverse It was all that restrictive feeding-by-the-clock and frustration of the infants' hunger that produced the ten million insatiable adults If you allow the self-demand principle in infancy, the children will grow up to be emotionally more stable, less demanding, and generally better controlled "

O K Then in a few years there won't be any obesity I, for one, am quite prepared to wait and see if the proof of the pudding is in the eating

* * *

All good general practitioners are ready-witted and resourceful, and it is my secret sorrow that the years have taught me the right things to say and do—always about a day too late Except once

In my practice in the country I used to reserve a quiet hour or two on Sunday mornings for benevolent but time consuming procedures, one of which was tapping hydroceles A village ancient arrived for the biennial removal of his half pint and, as an old customer, fetched his basin and perched on the stool Always tender hearted, I inserted the smallest possible trocar and left him to drain as usual

I lived then in a big rabbit warren of a house with a large garden and orchard behind it It was a lovely morning in early summer so I wandered into the garden to while away the necessary ten or twenty minutes The air was fresh and sweet, and the sun was drying the dew on the petals of my roses My lovingly nursed rhododendrons gave promise of a wondrous beauty I found a rare catch of earwigs in the traps on my dahlia stakes, and there was a purposeful hum about my beehives A garden offers much to tempt the mind and I mused my way round the orchard and thought of many things Everything in fact except what I ought to have thought of

I was jerked back to the rude earth by an alarmed wife with a tale of a strange man wandering round the house calling for me in a loud voice Like a schoolboy who has overstayed his playtime, I hastened guiltily back meeting on the garden path the ancient who by this time had rambled through the house and discovered the back door He held the trocar in place with one hand and did his best to support his trousers with the other, and he moved with a gait undescribed in any textbook Then it was that for once in my life my grey cells worked at speed Tut tutting impatiently, I hustled him back to his stool where I made him perch another few minutes while the last few, but most important, drops of fluid came resumed virus origin. In the two years there were nfections with *Leptospira icterohæmorrhagiæ* and 12 h *L. canicola*. No other strain has been identified in at Britain.

he figures included under mumps in table II refer only patients who were negative in the other tests, who had history of mumps, and in whom a pair of sera were ted. It does not include sera in which there was an changing titre in two specimens which made accurate erpretation impossible. Great difficulty can arise ring the poliomyelitis "season" if mumps-meningitis curs without parotitis. Sera may be obtained too late the illness to demonstrate a rising titre; and. until itable tests for poliomyelitis are available, it will be possible to make a certain diagnosis in such cases ith a high but unchanging titre of mumps antibodies. e have also received sera from a patient with menin-tis who was a household mumps contact but was roved to be a case of leptospirosis (*L. canicola*).

In 1949 there were no rising titres for mumps virus in atients without parotitis. In 1950 only 2 of 73 had ising titres. These were in children aged five years with lnesses in June and July. In addition there were 4 atients with positive sera who had a history of mumps rom seven to fourteen days before admission with meningitis.

In both the L.C.M. and the leptospiral groups the roportion of positive results was four or five times greater in paired sera than in the single convalescent specimens. This suggested that pairs of acute and convalescent sera were collected more often from the more typical cases, whereas the single specimens were from cases in which the diagnosis "virus" was an afterthought.

In virus infections involving the central nervous system recent, past but recent, or simultaneous infection with two or more viruses, or with viruses and leptospira, are liable to cause considerable difficulty in diagnosis. Thus, mumps may occur in a household with a dog excreting *L. canicola*: poliomyelitis may occur in a similar household: poliomyelitis and Coxsackie viruses have often been found together in fæces as well as a rise in titre of antibodies to both viruses at the same time. A precise diagnosis may be virtually impossible in such cases.

SUMMARY

The results of the use of serological tests in the diagnosis of suspected virus diseases in 1660 patients with affections of the respiratory tract, and 334 with affections of the central nervous system in 1949–51, are briefly described.

As has often been emphasised in other similar reports, two samples of serum showing a rising titre of antibodies are essential for a definite diagnosis of the current illness.

The largest proportion of sera examined were from patients with presumed virus infections of the respiratory tract, mainly pneumonia. The results indicate that the sera from such patients with suspected virus infection in Great Britain, should be tested for antibodies to *Strep. M.G.*, influenza viruses, the psittacosis-L.G.V. group of viruses, and *R. burneti*.

Suspected virus infections of the central nervous system can be investigated for antibodies to mumps and L.C.M. viruses and leptospires. Serological tests for poliomyelitis will probably be available in the near future. If these tests give negative results, tests for herpes virus and toxoplasmosis may help the diagnosis.

NEW YEAR HONOURS

The list of honours published last week contains the names of the following members of the medical profession:

Order of Merit

Wilder Graves Penfield, C.M.G., M.D. Johns Hopkins, D.SC. Oxfd, F.R.C.S., F.R.S.
Professor of neurology and neurosurgery, McGill University, Montreal.

K.C.M.G.

Eric Denholm Pridie, C.M.G. D.S.O., O.B.E., M.B. Lond.
Chief medical officer, Colonial Office.

K.B.E. (Military)

Lieut.-General Frederick Harris, C.B., C.B.E. M.C., M.B. Dubl., Q.H.S.
Director-general, Army-Medical Services.
Surgeon Vice-Admiral Kenneth Alexander Ingleby MacKenzie, C.B., B.M. Oxfd.
Medical director-general, Royal Navy.

Knights Bachelor

Vincent Zachary Cope, M.D., M.S. Lond., F.R.C.S.
Consulting surgeon to St. Mary's Hospital, London.
Arthur William Mickle Ellis, O.B.E., D.M. Oxfd, F.R.C.P.
Emeritus regius professor of medicine, University of Oxford; consulting physician to the London Hospital.
Norman McAlister Gregg, M.C., CH.M. Sydney, F.R.A.C.S.
Ophthalmic surgeon, Royal Prince Alfred Hospital, Sydney.
Edmund Britten Jones, M.A. Oxfd, M.B. Adelaide, F.R.C.P.
Consulting physician. Adelaide Children's Hospital.
Peter MacCallum, M.C., M.A.N.Z., M.D., M.SC. Melb., F.R.A.C.P., M.R.C.P.E.
Formerly professor of pathology and dean of the faculty of medicine, University of Melbourne.

C.B. (Military)

Major-General Arthur Joseph Beveridge, O.B.E., M.C., M.SC., M.B. N.U.I., Q.H.P.
Surgeon Rear-Admiral Thomas Norman D'Arcy, C.B.E., L.R.C.P.I.
Air Vice-Marshal Edward Demetrius Dalziel Dickson, C.B.E., M.D. Edin., F.R.C.S.E., Q.H.S.
Consultant in otorhinolaryngology, R.A.F.
Major-General Frank Kingsley Norris, C.B.E., D.S.O., M.D. Melb.
Director-general of Medical Services. Australian Military Forces.

C.M.G.

Alfred Edward Rowden White, M.D. Melb., F.R.A.C.P.
Consulting physician, St. Vincent's Hospital, Melbourne.

C.M.G. (Honorary)

Samuel Layinka Ayodeji Manuwa, O.B.E., M.D. Edin., F.R.C.S.E.
Inspector-general of Medical Services, Nigeria.

C.B.E. (Civil)

Ivor Jones Davies, M.D. Lond., F.R.C.P.
Consulting physician, Ministry of Pensions Hospital, Rookwood, Cardiff.
John Lowe, M.D. Birm., M.R.C.P.
Senior specialist, Nigeria Leprosy Service.
Robert Alexander McCance, M.D. Camb., F.R.C.P., F.R.S.
Professor of experimental medicine, University of Cambridge.
Charles Lindsay Sutherland, O.B.E., M.D. Glasg.
Senior medical officer, Ministry of National Insurance.
Arnold Learoyd Walker, M.B. Camb., F.R.C.S., F.R.C.O.G.
Chairman, Central Midwives Board.
Robert Weaver, M.D. Belf.
Senior medical officer, Ministry of Education.

O.B.E. (Military)

Lieut.-Colonel Morris Sutherland Worgan Bisdee, M.R.C.S., R.A.M.C.

O.B.E. (Civil)

Reginald Norris O'Connell Blanc, M.B. N.U.I.
Senior medical officer, Colonial Medical Service, Tobago.
Eric Lauder Caldwell-Smith, M.B. Camb.
Chief medical officer, Shipping Federation Ltd.
John Singleton Darling, M.B. Belf., F.R.C.S.
Surgical specialist, Overseas Food Corporation.

TABLE I—DISTRIBUTION OF POSITIVE SERA AMONG ONLY THOSE PATIENTS FROM WHOM ADEQUATELY PAIRED WERE OBTAINED AND A FOURFOLD OR GREATER RISE IN TITRE DEMONSTRATED

Diagnosis	Influenza			Q fever	Psittacosis	Strep M G	Negative	T
	A	B	Total					
"Influenza" "Febrile catarrh" "Acute bronchitis"	34	18	52 (39%)	1 (0 7%)	0	3 (2%)	76	1
Lobar pneumonia	7	1	8 (10%)	0	1 (1%)	2 (2%)	72	[illegible]
Bronchopneumonia	3	1	4 (7%)	0	1 (2%)	1 (2%)	47	[illegible]
Virus or primary atypical pneumonia	11	8	19 (8%)	22 (9%)	2 (1%)	38 (16%)	160	[illegible]
P U O	0	3	3 (7%)	2 (5%)	1 (2%)	1 (2%)	35	[illegible]
Total			86 (16%)	25 (6%)	5 (1%)	45 (8%)	390	[illegible]

infective agent or may have been examples of aspiration pneumonia Of the patients diagnosed as having influenza, bronchitis, or febrile catarrh, about 39% had evidence of infection with influenza virus A or B These positives were confined to times of epidemic prevalence Evidence of infection with influenza virus was distributed fairly generally among diagnoses other than "influenza" and similarly confined to the epidemic period The incidence of Q fever was highest in the groups diagnosed initially as virus pneumonia or pyrexia of unknown origin By contrast, the incidence of infection with the psittacosis-L G V group of viruses, as determined serologically, was fairly evenly distributed between clinical diagnoses The incidence of *Strep M G* reactions was greatest (16%) in the group diagnosed clinically as virus or atypical pneumonia (Tests for cold agglutinins were usually made by the laboratory forwarding the sera, the Virus Reference Laboratory made these tests on only a small proportion of sera received direct from practitioners)

The influenza cases occurred, as already stated, during certain limited periods of three or four months in the two winters Cases of infection with the psittacosis-L G V group of viruses and with *R burneti* were distributed fairly evenly throughout the period Infection with agents causing illness characterised by the presence of cold hæmagglutinins or agglutinins to *Strep M G* was detected throughout the year but was more prevalent during the late summer and the winter months

It is obvious that, by chance, dual or even triple infection with these agents could take place, especially during the epidemic prevalence of influenza or of infection by *Strep M G* Thus, a resident in an area where there are cows or other animals infected with *R. burneti* might keep pigeons with ornithosis and himself be exposed to influenza Such a patient was seen at the beginning of May, 1950 This man, employed at a glass works, experienced on May 10 a cold and slight fever from which he recovered in two days On May 19 he became ill with severe headache, shivering, sweating, and pyrexia, clinically typical of Q fever Serological investigation of sera showed the following results

*Day**	*Complement fixation tests*				*Agglutination to Strep M G*
				Psittacosis	
7	<4†	32	<8	<10	<10
14	<4	32	32	20	<10
23	<4	32	256	20	<10

*From onset of second illness † Reciprocates of the titre

The rising titre of *R burneti* antibodies indicates that this patient had Q fever, which diagnosis was supported by the finding of two other cases of Q fever in the household Possibly the influenza-B antibodies were due to upper respiratory infection on May 10 If the tests had only been made for influenza, post-influenzal pneumonia might have been diagnosed The slight rise in titre to the psittacosis-L G V group of viruses possibly represents an anamnestic reaction, since the patient had kept pigeons in the past

Two cases of glandular fever with pneumonia were diagnosed during the period One had been diagnosed clinically as Q fever

CENTRAL NERVOUS SYSTEM

Most viruses are known to be able to cause vari degrees of infection of the central nervous syste particularly meningitis or meningo-encephalitis, but on a few of those viruses for which tests are available hav been shown to be responsible for a significant percenta of these cases During the period from January, 194 to December, 1950, it was possible to make compleme *fixation tests only for L C M and mumps and agglutinatio* tests for leptospires as a routine in cases diagnosed a benign aseptic meningitis, virus meningitis, meningo-encephalitis, or non-paralytic or abortive poliomyelitis A few patients were also tested for influenza, psittacos herpes, and Q-fever antibodies with negative results, and these tests are not included in table II Tests for thre strains of Coxsackie-A viruses were also made in some patients diagnosed as having aseptic meningitis o abortive poliomyelitis Complement fixing antibod were present in some sera to Dalldorf's group A, typ 1 and 2, and Melnick's High Point strain, but no new titres were found Neutralisation tests for Coxsackie viruses were not made in this period No satisfactory serological tests for poliomyelitis were available then

The results of tests on 138 patients in 1949 and 19 in 1950 from whom satisfactory samples of serum wer obtained are seen in table II They include results o patients from whom paired sera or one or more conva*lescent specimens* were received The sera were tested first for leptospires and L C M, and the negative ones the tested for mumps, so the latter series is smaller

There is no obvious explanation for the rise in the percentage of L C M *positives* in 1950 over 1949 other *than a possible increasing interest in the diagnosis* of L C M on the part of physicians The 19 patients in 1950 with either a rising titre (13) or positive convalescent serum suggesting recent infection with this virus cam from nineteen different localities, but 1 came from th same street as one of the 1949 cases

The proportion of leptospiral infections in 1950 (4·0%) was lower than in 1949 (7 7%) This may be due partly to the increasing recognition by doctors of the possibility of this organism being responsible for this type of meningitis with the result that many more sera were sent direct to Dr Broom and did not first pass through our hands as specimens from lymphocytic meningitis

TABLE II—RESULTS OF SEROLOGICAL INVESTIGATIONS FOR MUMPS, L C M, AND LEPTOSPIRAL ANTIBODIES IN PATIENT WITH SUSPECTED VIRUS INFECTION OF CENTRAL NERVOU SYSTEM OF UNKNOWN ÆTIOLOGY

Year	No examined	Mumps		L C M		Leptospirosi	
		No tested	No positive	No tested	No positive	No tested	No positive
1949	138	51	0	132 [134]	3* (2 2%) [5† (3 7%)]	130	10 (7 7%)
1950	196	73	2 (2 7%)	185 [191]	13* (7 3%) [19† (10 0%)]	196	8 (4 0%)

* Number with rising titres in two or more sera
† Total no of positives including single specimens or unchangin titres in paired sera

away. He was apologetic. He didn't know, perhaps I had forgotten—more tut-tutting from me—anyway, he meant no harm.

To those of ready wit and resource it would have been a trifle. But to me, with my moss-grown mentality, that little episode represents the red-letter day when I finished master of the situation.

* * *

Do you remember the story of the old Negro slave apprehended for having run away? "I can't understand you," said the judge petulantly: "you had a good master, plenty of food, a bed to sleep in." "Well, boss," retorted the Negro, "the situation's still open if you want it." And therein I think he epitomised the whole philosophy of living. How easy it is to make rules for other people. In the same way we contemplate with surprise the dissatisfaction of those who seem to have everything that anyone could wish. Probably they have everything except the one thing that they really desire. A nobleman with wealth, intellect, physical beauty, good health, charm, and apparently domestic happiness craved for one thing and would be satisfied with only that—to win the men's singles at Wimbledon. Could I help him, physically, psychologically, any way? Only after years of disappointment did he admit the impossibility, and it will be a poignant regret for the rest of his life. The richest man in our profession was disgruntled because he failed to secure a large consulting practice. A great lawyer whose success was the envy of all his professional brethren, whose ability to sway by his eloquence ought to have given him the most wonderful sense of power, fumed and fretted at his inability to lower his golf handicap below 14.

The more one is admitted to the secret ambitions of the great, the less one finds to envy, the more one realises the profundity of the banal truism that it is not what you have but what you are satisfied with that really counts.

* * *

A junior colleague of ours was recently assigned to the tropics, and the veterans among us gave him the usual hints and tips. Most of us knew there was a medical school out there, though none of us had seen it. Exact information could, of course, have been found in the *Universities Yearbook*, but being doctors we didn't know it existed. And so, when our friend said he was taking them a current textbook of medicine, we agreed it was a kindly thought, and that the East would know how to value this fraternal gesture from the West. Indeed it did, as we learned on our colleague's return at the end of the session. He was bronzed and fit, but much quieter than he used to be—not quite the debonair Empire-builder we had said goodbye to. "Well, what sort of a joint was it?" we asked. "A swell set-up—in fact they're better equipped than we are. New buildings, you know, with first-class research facilities, and all sorts of gadgets and fittings that this university's never heard of." "But surely the staff must be rather mothy?" "Mothy? They're all two-fellowship men." "You mean Eng. and Ed.?" "No, Lond. and Eng.—you can't tell the physicians from the surgeons." "And what about the book?" "They were quite nice about it, but a consignment of it had got there before I did. 'If you don't want your copy,' they said, 'it would be appreciated by the Women's Institute—they're all medicine-minded now, and like to catch the radio and television doctors out. Or there's the grammar school—they'd welcome it, since we gather that medicine is soon to be recognised as a G.C.E. subject.' 'Thanks for these happy suggestions,' I replied, 'but I think I'd better read it myself.'"

Our general conclusion is that the Empire, far flung though it be, is now (culturally speaking) a built-up area, and that there's really no place like home.

* * *

Overheard at a forensic examination

Examiner: Dissertate on this rag.
Candidate: It's bloodstained, Sir.
Examiner: Good. How old is the stain?
Candidate: A little over six months, Sir.
Examiner: Very good, but how do you know that?
Candidate: You showed me the same rag six months ago, Sir.

Letters to the Editor

THE NURSE'S RESPONSIBILITY

SIR,—May I comment on your leading article of June 6? With reference to the disaster you cite, I cannot believe that anyone in the medical-nursing team can be exonerated from blame for failure to read and understand the label of any container of drugs or products to be administered to a patient. The fact that the responsibility of administration ought not to have been delegated does not lessen the blame for the omission. It would seem to be almost as fundamental to expect that enough of the drug or medicament required should be available before the treatment is begun.

The estimation of blood-pressure has for some time been included in the course of training for pupil-midwives, whether registered nurses or not (C.M.B. rules B 36 (*d*)). The syllabus of subjects for examination for the certificate of general nursing requires "taking and recording blood pressure" (G.N.C. England and Wales, 1952, final examination VII). Preparation for intravenous injection is also to be taught. As long ago as 1937 a doctor writing in the *Nursing Times* (Dec. 25) criticised the training of English nurses and pointed out that in France intravenous injections are generally given by the nurse, rarely by the doctor.

This raises the question of the proper duty of the nurse. Obviously a nurse in training should be taught only those skills and techniques ordained by the registering body and should never be asked to perform as an employee what she may not be taught as a student. But once the nurse is trained and registered it would be difficult to agree that she should never undertake what she did not learn while training, or any technique not mentioned in a syllabus which may have been drawn up years ago. The essential requirements seem to be: (1) that the decision to permit a nurse, or other person in the ward team, to perform a procedure shall be a result of deliberate policy, arrived at by discussion between all the persons concerned, including the body having ultimate responsibility; (2) that the technique must have been thoroughly learned and practised until the requisite skill is attained and is known to have been attained; (3) that whenever it is foreseen that a nurse or other person, who does not normally apply a particular technique, may be called on to apply it in an emergency, or in the absence of the person who usually undertakes it, she must have received the necessary training. Otherwise an emergency may become a disaster.

Drugs, procedures, skills, and techniques are changing and developing so rapidly that it would seem imperative that the nursing councils should have permanent curriculum committees, whose business it would be to issue from time to time "addenda" on training between the periodical reviews of the entire curriculum and syllabus.

Edinburgh. G. B. CARTER.

SIR,—I read with interest and concurrence your leading article, and I also read a reply last week by Dr. R. E. Smith.

We, in the nursing profession, do realise how busy the house-physicians and house-surgeons are, and we would help in all possible ways to lighten their load provided this does not entail neglecting nursing duties. The State-registered nurse not only nurses her patients but also helps in the training of the student nurse, and I feel that the satisfactory fulfilment of these duties constitutes a full-time job.

Who will be held responsible if a patient develops a bedsore? The nurse, because she has failed to carry out her nursing procedures adequately, or the doctor, because he has prevented her from so doing by adding

HEADACHE AND HYPERTENSION

I McD G Stewart
M D Lond , M R C P

MEDICAL REGISTRAR UNITED BRISTOL HOSPITALS ,
UTOR IN MEDICINE UNIVERSITY OF BRISTOL

nt years fresh efforts have been made to treat ion by arbitrary reduction of the blood-pressure , and indeed with some success By sympathectomy, or treatment with drugs, not only has it proved possible to lower the pressure, at least temporarily, but also left ventricular failure has been observed to recover, heart size to diminish, fundal changes to regress and electrocardiographic abnormalities to return to normal At the same time paroxysmal breathlessness has been overcome and vision improved These are substantial benefits Unfortunately they are seldom achieved Many claims to success have been based upon less substantial grounds They have derived solely from the alleged cure of symptoms. But of what exactly, had these patients complained ? What are these "symptoms of hypertension" ? Do they indeed exist apart from those disorders of organs which accompany or complicate the course of hypertensive disease ?

Clearly some doctors believe that they do The most highly accredited symptom is "headache" Others widely acknowledged include "dizziness" "lack of energy," and "lack of concentration" The cure of such complaints has often been taken to prove the worth of a treatment More than one remedy has claimed support solely on the strength of its reputed efficacy in the "relief of symptoms"—the particular ills so ameliorated remaining unspecified

This kind of language has appeared repeatedly in the medical literature during the past few years Even Smithwick (1940), who first popularised splanchnic sympathectomy, scarcely defined the "symptomatic relief" which he designated one of the important objects of surgery , admittedly his main intent was to offer an improvement in survival-rate Many of his followers have been less restrained

For example, no misgiving prevented FitzGerald (1950) from proclaiming his view that "symptomatic relief is one of the greatest blessings conferred by sympathectomy symptoms determine the operability one frequently operates for their alleviation alone This is a simple but well proven maxim" He did not define these symptoms His contention, in common with that originally put forward by Smithwick (1948) was that operation should be undertaken early Clearly, therefore, they could not have been caused by heart failure, uræmia, or hypertensive retinopathy such are late events in the disease

"Shortness of breath. intellectual decline, and irascibility " were said by Atkins (1950) to have been evident among his hypertensive patients, many of whom, nevertheless, "complained mainly of headache" Hammarström and Bechgaard (1950) defined a group of hypertensives in whom there were "marked subjective symptoms but without signs of myocardial damage", on the strength of this criterion these hypertensives were subjected to surgery Yet the symptoms thus held to have been so significant could scarcely have included paroxysmal dyspnœa or visual disability, since pulmonary œdema consequent on hypertension, and retinal changes sufficient to affect vision, are, again, virtually always accompanied by the appearances of myocardial strain or failure

Chris (1951) accepted "severe headaches" as one of the most important of "definite symptoms referable to hypertension," thereby constituting an indication for sympathectomy Allen (1952), however, has reported that American surgeons have recently lost some of their enthusiasm for sympathectomy as a means of dealing with "hypertensive headache"

Most of the physicians who have conducted trials with the new methonium drugs have written in similar vein.

Thus Murphy (1951) reported that "symptomatic improvement was impressive" in most of his cases, while Mackey and Shaw (1951) maintained that "of all the manifestations of hypertension headache is the most easily relieved"

Smirk and Alstad (1951) were satisfied about the benefit to "headache, dyspnœa, and vertigo" A few months later Smirk (1952) gave as the main hope offered by prolongation of the action of hypotensive drugs the prospect that more relief might be afforded to the 10% of hypertensive patients whose headaches are at present insufficiently relieved"

Much the same type of claim has been advanced on behalf of the rice diet treatment originally suggested by Kempner A report published by a committee of the Medical Research Council (1950) included the sentence "Of 33 patients with symptoms referable to hypertension 25 (75%) obtained relief Headaches, which were present in 26, disappeared in *all but 4, often within a few days of starting the diet*"

It cannot be denied that people who have hypertension are liable to complain of headache, to experience dizziness and shortness of breath, even to lose their tempers Such distresses, however, are not unusual It does not follow that the blood-pressure is in any way to blame To establish a sequence of cause and effect more evidence is required Can there be demonstrated any clear relation with hypertension ? Is there, perhaps, a type of headache that is characteristic of hypertensive disease ?

Despite the confident assertions that have been quoted these are disputed questions

For example, Russell Brain (1952) writes "High blood-pressure causes paroxysmal, throbbing or 'bursting' headaches," and Platt (1950) asserts that "true hypertensive headache may be frontal or occipital and is usually most prominent in the early morning" Alexander (1948), in common with many other writers, has drawn attention to a parallel with migraine

Symonds (1946), however, contents himself with the more cautious statement that "headache is a common but inconstant symptom of arterial hypertension," while making the reservation that he is excluding from consideration the "relatively rare condition known as hypertensive encephalopathy" Wood (1950a) goes further and declares roundly that "it is doubtful whether any symptoms can be ascribed to high blood pressure itself" Others have agreed with this view

It was in an attempt to clarify this association between high blood-pressure and the symptoms that so often accompany it that the following clinical study was undertaken Particular attention was paid to the significance of headache

Scheme of Investigation

The study was made upon 200 consecutive cases of severe hypertension and upon a number of controls All the patients were interviewed and examined by me Among the hypertensives the only criterion of selection was the height of the diastolic blood-pressure The standard adopted was a minimum of 120 mm Hg, measured with the patient recumbent, after ten minutes' rest in that position Whenever a reading had been made previously by another observer, the level then noted had nearly always been considerably higher than that obtained by this routine technique Occasionally the pressure was found at a subsequent examination to have fallen below 120 mm Hg Unless there had been obvious cause for this—e g , intervening cardiac infarction—all record of the patient was expunged from the survey. It was thought best to abide by the blood-pressure alone as a standard for inclusion in the series Inevitably, however, this led to the omission of a few patients who, though clearly severely hypertensive, never presented a sufficiently high diastolic level, because when they were first seen, they had cardiac failure, recent infarction, or some similar complication

The following points were determined

(1) Whether or not the patient was aware of the raised blood pressure

(2) The volunteered symptoms, if any, in the order in which they were volunteered

special techniques to her already over-full programme? It is a question not only of legal responsibility—although this is a serious consideration—but of allowing the nurse to nurse her patients. She does not want to become a technician.

The nurse is adequately equipped to take her place after registration in a surgical or medical ward. She will increase her value to her patients and to the senior staff when she gains experience in that particular ward or department, but I deprecate the suggestion that she should specialise and be expected to carry out special procedures.

If the time is ripe, as Dr. R. E. Smith suggests, for another Commission on Nursing, let this be set up by the nurses of the country.

South Devon and East Cornwall Hospital, Plymouth. ANN G. NOTMAN Sister Tutor.

TUBERCULOSIS IN GLASGOW

SIR,—Dr. Paul's letter last week does not contain any convincing evidence that social improvements can eradicate tuberculosis. In 1950 over 14,000 people in England and Wales died of tuberculosis: if this death-rate was one-tenth of the death-rate a hundred years previously, it does not demonstrate a satisfactory position in 1950, but emphasises how dreadful tuberculosis was in 1850. Any complacency, therefore, is Dr. Paul's, not mine.

It is from the behaviour of the tuberculosis death-rate in the past five years, however, that the most valuable lessons can be learned. In Northern Ireland, where the trend has been similar to that in the rest of the United Kingdom, this rate was 73 per 100,000 in 1947. In 1952 it was approximately 30 per 100,000. In the intervening five years as much had been achieved in reducing tuberculosis mortality as in the previous forty years. Furthermore, the reduction in the number of deaths has been accompanied by a reduction in the number of new cases which are being discovered. The present position is directly related to the vigorous efforts of the Northern Ireland Tuberculosis Authority since 1947 to provide for the diagnosis and treatment of tuberculosis in the Province, and we are now in a position to measure our progress towards eradication not in generations and centuries but in single years. It is quite true that for many of our patients the new drugs have postponed death and that tuberculous lesions can relapse; but life for all of us is a postponement of death, and if, after treatment, a tuberculous patient can be restored to normal health, it is not of great importance whether we say that his death has been postponed or that his life has been saved.

I am not as ignorant of the epidemiology of tuberculosis in other countries as Dr. Paul might think. The high standard of living in Scandinavia has been accompanied by a high rate of hospital building, and as far as I know there has never been a waiting-list for Scandinavian chest hospitals. While the new drugs have made the treatment of tuberculosis infinitely more efficient, it was far from being ineffective before. The countries, therefore, in which the isolation and treatment of the majority of their infectious cases of tuberculosis have always been possible are certain now, with the addition of modern discoveries, to have less tuberculosis than elsewhere.

It is not possible here to explore the vast subject of the immunology of tuberculosis. It should scarcely be necessary to remind Dr. Paul that measures which are effective in abolishing one infectious disease are not necessarily effective against another, and that the tubercle bacillus shows certain important differences from the diphtheria bacillus. The majority of deaths from tuberculosis occur in those sections of the population which contain the largest numbers of positive reactors to tuberculin, and if a positive tuberculin test as a indication of acquired resistance is compared to a negativ Shick test, this would mean that the greatest number o deaths from diphtheria should occur amongst thos groups containing the largest numbers of negativ Schick-reactors, which is obviously absurd. The mechanism of acquired resistance to tuberculosis, therefore is quite different from that of any other disease, and I share Dr. Paul's appreciation of the irony of injectin live tubercle bacilli into the non-tuberculous subject of civilised nations. I can give details to Dr. Paul, if he would like to have them, of other civilised nations in which tuberculosis is being controlled by the isolatio and treatment of infectious cases, in which a positiv tuberculin reaction is regarded as a danger and no a blessing, and in which the complete eradication o tuberculosis is already in sight.

I have not been trailing my coat, and there wa nothing particularly astonishing about my previou letter. It could provoke only those who have not realised yet that there has been a scientific revolution in the treatment of tuberculosis. This revolution demands a new approach to the disease and a re-examination of previous theories, however sanctified they may have become by the passage of time and the prestige of those who hold them. It is clear to me, as it is to any clinician who pauses to look around him, that we have within our hands the means of abolishing tuberculosis and of making a tremendous contribution to human happiness. But we must not be obstructed. If we are given the tools we can finish the job.

Dungannon Chest Hospital, co. Tyrone. E. F. JAMES.

MITRAL STENOSIS

SIR,—In their very interesting and inspiring paper (May 30) Mr. Logan and Dr. Turner do not mention simple venesection in the treatment of acute pulmonary œdema. In my experience withdrawal of 300 ml. of blood is the quickest and safest way of bringing out of immediate danger a patient with acute pulmonary œdema.

Municipal Hospital, Aalborg, Denmark. CARL SCHWENSEN.

PHARMACEUTICAL ADVERTISEMENTS

SIR,—Much of the costly advertising matter which is causing so much concern to your readers must be regarded as a direct consequence of the N.H.S., which has attracted into the so-called "ethical" pharmaceutical trade a great number of firms with no real roots in the industry. Thus there are makers of various useful household goods and foods who are exploiting commonplace preparations of well-known drugs with the simple ferocity with which they would otherwise be marketing furniture-polish or stocking dyes. To make a nationally advertised nostrum acceptable for N.H.S. prescribing, all that need be done is to register another trade mark and suitably adjust the package.

Another contributory factor is the fact that many minor firms of wholesale druggists, who formerly reaped a comfortable but unspectacular revenue from materials for medical dispensing (e.g., mist. expectorans 1-8), have had this relatively harmless activity dislocated by the N.H.S. and have had to buy a battery of tablet-machines and the services of an advertising agent to make up for the consequent loss of trade.

Prescribers sometimes seem to me to take an irrational pride in their ignorance of the composition of the preparations they prescribe; they should, at least, attempt to learn a little about the status and antecedents of their manufacturers. For example, Megatherium Pharmaceuticals (1947) Ltd. undoubtedly spend a great deal of money on research—*market* research. Their most highly paid technician is the sales manager, who is *often* director of pharmacological research as well. His chief reason for

Faculty of Radiologists

The annual meeting of the faculty will open at the Royal College of Surgeons, London, at 9 30 A M on Friday, July 3, and will continue on July 4

Lady Tata Trust

The trustees of this fund announce that they have made the following awards for research on leukæmia and allied diseases, in the year beginning next October

Grants for research expenses or for scientific assistance—Dr Astrid Fagraeus and Dr Bo Thorell (Stockholm), Dr Clarence Mershey (Cape Town), Prof. Charles Oberling (Paris), Dr C C Ungley (Newcastle upon Tyne), Dr Jo Nordmann (Paris)

Part time personal grant—Dr J B G Dausset (Paris)

Scholarships—Dr Ragna Rask Nielsen (Copenhagen) Dr Roger Robineaux (Paris), Dr Flemming Kissmeyer Nielsen (Aarhus, Denmark), Dr N A Stenderup (Aarhus, Denmark)

Senior Research fellowships—Dr A R. Gopal Ayengar (India) for work at the Royal Cancer Hospital, Dr Jorgen Kieler (Denmark) for work at the Fibiger Laboratories Copenhagen

A special scholarship awarded to Dr Gavino Negroni (Italy), for work at the Imperial Cancer Research Fund Laboratories, will continue until April 30, 1954

Beit Fellowship for Medical Research

The following awards have been made

Fourth-year Fellowship

JOAN E KEILIN MA, MB, PHD Camb To investigate the catalytic activity of hæmatin compounds and the effect of oxidising agents on hæmatins Also to investigate the properties of purified helicorubin and its relationship to other natural hæmoproteins and to investigate the reactions of hæmatins with proteins and their constituent amino acids and peptides to gain more information as to the structure of the hæmoglobin molecule and the link between the hæm and globin and to use hæmatin as a reagent for the study of other biologically important proteins At the Department of Biochemistry, Cambridge

Junior Fellowships

J R. CANNON, M.SC, Sydney To continue the study of the chemical structure of Vitamin B_{11} At University Chemical Laboratories, Cambridge

G P LEWIS B PHARM Wales To study the relationship between structure and action of drugs particularly of antagonists of histamine, acetylcholine adrenaline and noradrenaline, to examine how far ionisation of a drug or its receptor modifies drug action At the National Institute for Medical Research, Mill Hill London

W L NICHOLAS, B SC Lpool To investigate the determination of the growth requirements of free living and parasitic nematodes in chemically defined media with a view to its possible application to the chemotherapy of nematode infections At the Department of Zoology, Liverpool University

EVELYN E B SMITH, B.SC PH D Glasg To investigate the enzymic mechanisms of transfer reactions involving uridine pyrophosphate compounds containing glucose, glucuronic acid, and N-acetylglucosamine and the biosynthesis of glucuronic acid, glucuronides, and oligosaccharides containing glucuronic acid, using carbon and phosphorus isotopes At the Department of Biochemistry, Glasgow University

South Western Regional Hospital Board

The Minister of Health has appointed Sir Havergal Downes Shaw, O B E, to be chairman of this board Sir Havergal Downes Shaw, a former departmental manager of the Imperial Tobacco Company, has been a member of Bristol City Council since 1931 and an alderman since 1946

Society for Relief of Widows and Orphans of Medical Men

This society s annual meeting was held on June 10, with Sir Robert Young, the president, in the chair Members of the society number 198, and at the end of 1952 there were 35 widows in receipt of grants Widows over 65 receive £75, and those under that age £60 a year In addition a present of £30 was made at Easter, and again at Michaelmas The total amount distributed in 1952 was £4525 Sir Ernest Rock Carling, the treasurer, reported that during the year income exceeded expenditure by £723 The address of the society is 11, Chandos Street, London, W 1

Institute on Œsophageal Speech

An institute on teaching and improving œsophageal speech will be held on Aug 10–16 at the Cleveland Hearing and Speech Center, Cleveland, Ohio This institute is being sponsored by the American Cancer Society, the National Cancer Institute of Institutes of Health the Office of Vocational Rehabilitation, the Cleveland Otolaryngological Society, the Cleveland Academy of Medicine, and the Western Reserve University School of Medicine Non speaking laryngectomised persons may attend without charge They may be sent by surgeons, cancer societies, societies for crippled persons, and rehabilitation services Surgeons speech pathologists, and laymen are also invited to attend the sessions Application must be made by July 15 to Warren H Gardner, PH D program chairman 11206 Euclid Avenue, Cleveland 6, Ohio

Royal Medical Benevolent Fund

At the annual meeting, held on June 9, honorary of were re elected as follows president, Lord Webb-John treasurer, Mr F A Juler, secretary, Dr R Cove Smith

International Hæmophilia Society

A meeting of this society is to be held at Seymour H London, W 1, on Sunday, June 21, at 2 P M The Lond Group will meet at the society's offices, 94, Southwark Brd Road, S W 1, on Wednesday, July 1, at 6 30 P M

Visitor in Lunacy

The Lord Chancellor has appointed Dr R G Ander a commissioner of the Board of Control, to be a medical v in the place of Dr A E Evans who is retiring

Oxford Graduates Medical Club

The summer dinner will be held in the Queen's Colle Oxford, on Friday, July 10, at 7 for 7 30 P M Dr C G Douglas, F R S, will preside Tickets (£2 2s inclusive) m be had before July 4 from Mr Selwyn Taylor, F R C S, Roedean Crescent, London, S W 15

including some new component in a remedy may be to give his advertisement copywriters something to work on.

It would be, of course, both impracticable and undesirable to try to enforce any kind of closed shop in the pharmaceutical industry. Only an undischarged bankrupt is at present restricted from evolving some new formula of analgesics and sedatives and launching it on to the nation's drug bill with costly advertising. But prescribers should learn to recognise the comparatively few drug firms which make a real contribution to medicine through original research, and adjust their prescribing habits accordingly—and Megatherium Pharmaceuticals (1947) Ltd. should return to their shoe-polish, home perms, or whatever their proper line of country may be.

London, W.5. JOHN LOTHIAN.

BARBITURATES AND ALCOHOL

SIR,—In your annotation of June 6 you ask whether simultaneous intake of barbiturates and alcohol involves a grave risk of fatal poisoning, or whether the two fatal cases reported are merely examples of particular idiosyncrasies.

A comprehensive series of investigations into this question has been made here. We concluded, from clinical data and chemical analyses, that intake of relatively moderate doses of barbiturates and relatively large doses of alcohol may prove fatal, and that accordingly administration of barbiturates, especially intravenously, to severely intoxicated persons is extremely dangerous. This empirical material will be published later.

Further, we have shown that intake of alcoholic drinks by persons with chronic bromism may lead to death.

Even more important from a clinical point of view is our demonstration that injection of therapeutic doses of morphine salts (15–30 mg.) or of morphine-scopolamine in persons with 0·18–0·2% or more alcohol in the blood effects an often fatal poisoning with all the signs and symptoms of severe morphine poisoning. Within the past few years we have examined 16 fatal cases of this type. In several instances the drugs had been given as sedatives to persons who had been violent owing to alcohol intoxication.

A paper on our experiences concerning morphine in association with alcohol, published in Danish in December, 1952,[1] has been accepted for publication in the *Bulletin of Narcotics* United Nations, New York).

Department of Pharmacology,
University of Copenhagen. KNUD O. MOLLER.

EFFECT OF GLUTAMIC ACID ON THE COMA OF HEPATIC FAILURE

SIR,—I read with great interest the account by Dr. Walshe of the treatment of hepatic coma with intravenous sodium glutamate (May 30). This is undoubtedly of the greatest importance, especially as it applies to a group of cases with which my own régime[2] has not proved very successful. Like Karl et al.[3] I have seen only one recovery after coma due to hepatic cirrhosis.

Although sodium glutamate will be a welcome addition to our therapeutic weapons, I should like to emphasise that in the type of hepatic coma which we have been treating at Newcastle it will still be necessary to continue with a régime of the kind I have described. As your leading article (June 6) clearly states, the liver cells in acute necrosis are suffering from the effects of some acute noxa which does not persist. This almost certainly means that they require supportive therapy during the period of recovery.

Your article also lays stress on the importance of electrolytes in therapy. With this I fully agree. Not only is there the question of electrolyte disturbance owing to intravenous glucose, &c., but I have also on several occasions seen cases of postoperative liver-failure associated with biliary drainage, which had low serum levels of sodium and chloride, and which responded dramatically to the administration of hypertonic saline.

As the Newcastle series increases, the mortality-rate still remains somewhere between 10 and 20%. I believe that this is a distinct improvement on previous forms of therapy, especially as care is now being taken to include for statistical evidence only those cases in which massive amino-aciduria has been demonstrated by paper chromatography. The régime has been slightly modified in that after the first few days $^1/_5$ normal, and not normal, saline is now used. Gamma-globulin is also given in those cases where the hepatitis virus may still be active.

The therapy is still proving useful for liver-failure in obstetrics and in the preparation of patients for operation in the presence of jaundice. Other centres seem to be having similar success with both medical and surgical patients.

It is a pleasure once again to thank colleagues at the Royal Victoria Infirmary who have helped in this work.

TRANSPLANTATION OF HUMAN TUMOURS

SIR,—I was very interested to read of H. W. Toolan's success in transplanting human tumours into cortisone-treated weanling rats.[1]

Since October of last year I have been engaged in work under the direction of Prof. R. W. Scarff on heterologous tumour transplants, using various sites in mice and rats including the peritoneum, the anterior chamber of the eye, and the lens. The brain has also been used in adult irradiated and non-irradiated animals, and in these cases it soon became apparent that fibrous tissue appeared to grow down the needle track and surround the graft.

During discussions with my colleague Dr. J. B. Walter, it was agreed that corticotrophin and cortisone might inhibit the last reaction to the implant. Only a small quantity of cortisone was available, and therefore investigations were limited to a few animals.

The tumour used was a subcutaneous secondary "oat-cell" carcinoma removed by Mr. W. Grundill, at Harefield Hospital. Cortisone by subcutaneous injection was started three days before inoculation or implantation and continued daily. In a case where a small portion of tissue was implanted directly into the brain (using a technique similar to that of H. S. N. Greene[2]) the malignant and the fibrous tissue of the graft remained viable with little surrounding inflammatory reaction. This was twenty-six days after implantation.

In cases where cortisone was not started until five days after implantation the tumour showed almost complete regression after eleven days with marked surrounding cellular reaction.

In one case, where scrapings from the cut surface of the tumour were inoculated through the skull without drilling, there was histological evidence of vascularisation and invasion by tumour showing mitoses, some of which were aberrant. There was very little cellular reaction to the tumour in this case. The animal died on the thirteenth day after tumour inoculation.

Naturally, the significance of these isolated cases is impossible to assess, but in view of these and H. W. Toolan's work further investigation will be undertaken when cortisone is available. It may well be unnecessary to use weanling animals. The mice I used were thirty-four days old at the start of the experiments.

Other effects (presumably due to the cortisone) were a decrease in the total white-cell count with lymphopenia,

HEADACHE AND HYPERTENSION

I McD G Stewart
M D Lond , M R C P
MEDICAL REGISTRAR, UNITED BRISTOL HOSPITALS ,
UTOR IN MEDICINE, UNIVERSITY OF BRISTOL

nt years fresh efforts have been made to treat ion by arbitrary reduction of the blood-pressure , and indeed with some success By sympathectomy, or treatment with drugs, not only has it proved possible to lower the pressure, at least temporarily, but also left ventricular failure has been observed to recover, heart size to diminish, fundal changes to regress, and electrocardiographic abnormalities to return to normal At the same time paroxysmal breathlessness has been overcome and vision improved These are substantial benefits Unfortunately they are seldom achieved Many claims to success have been based upon less substantial grounds They have derived solely from the alleged cure of symptoms. But of what, exactly, had these patients complained ? What are these " symptoms of hypertension " ? Do they indeed exist apart from those disorders of organs which accompany or complicate the course of hypertensive disease ?

Clearly some doctors believe that they do The most highly accredited symptom is " headache " Others widely acknowledged include " dizziness," " lack of energy," and " lack of concentration " The cure of such complaints has often been taken to prove the worth of a treatment More than one remedy has claimed support solely on the strength of its reputed efficacy in the " relief of symptoms "—the particular ills so ameliorated remaining unspecified

This kind of language has appeared repeatedly in the medical literature during the past few years Even Smithwick (1940), who first popularised splanchnic sympathectomy, scarcely defined the " symptomatic relief " which he designated one of the important objects of surgery , admittedly his main intent was to offer an improvement in survival rate Many of his followers have been less restrained

For example, no misgiving prevented FitzGerald (1950) from proclaiming his view that " symptomatic relief is one of the greatest blessings conferred by sympathectomy symptoms determine the operability one frequently operates for their alleviation alone This is a simple but well proven maxim " He did not define these symptoms His contention, in common with that originally put forward by Smithwick (1948), was that operation should be undertaken early Clearly, therefore, they could not have been caused by heart failure, uræmia or hypertensive retinopathy such are late events in the disease

" Shortness of breath, intellectual decline, and irascibility " were said by Atkins (1950) to have been evident among his hypertensive patients, many of whom, nevertheless, " complained mainly of headache " Hammarström and Bechgaard (1950) defined a group of hypertensives in whom there were " marked subjective symptoms but without signs of myocardial damage " , on the strength of this criterion these hypertensives were subjected to surgery Yet the symptoms thus held to have been so significant could scarcely have included paroxysmal dyspnœa or visual disability, since pulmonary œdema consequent on hypertension, and retinal changes sufficient to affect vision, are, again, virtually always accompanied by the appearances of myocardial strain or failure

Chris (1951) accepted " severe headaches " as one of the most important of " definite symptoms referable to hypertension," thereby constituting an indication for sympathectomy Allen (1952), however, has reported that American surgeons have recently lost some of their enthusiasm for sympathectomy as a means of dealing with " hypertensive headache "

Most of the physicians who have conducted trials with the new methonium drugs have written in similar vein

Thus Murphy (1951) reported that " symptomatic improvement was impressive " in most of his cases, while Mackey and Shaw (1951) maintained that " of all the manifestations of hypertension headache is the most easily relieved "

Smirk and Alstad (1951) were satisfied about the benefit to " headache, dyspnœa, and vertigo " A few months later Smirk (1952) gave as the main hope offered by prolongation of the action of hypotensive drugs the prospect that ' more relief might be afforded to the 10% of hypertensive patients whose headaches are at present insufficiently relieved "

Much the same type of claim has been advanced on behalf of the rice diet treatment originally suggested by Kempner A report published by a committee of the Medical Research Council (1950) included the sentence " Of 33 patients with symptoms referable to hypertension 25 (75%) obtained relief Headaches, which were present in 26, disappeared in all but 4, often within a few days of starting the diet "

It cannot be denied that people who have hypertension are liable to complain of headache, to experience dizziness and shortness of breath, even to lose their tempers Such distresses, however, are not unusual It does not follow that the blood pressure is in any way to blame To establish a sequence of cause and effect more evidence is required Can there be demonstrated any clear relation with hypertension ? Is there, perhaps, a type of headache that is characteristic of hypertensive disease ?

Despite the confident assertions that have been quoted these are disputed questions

For example, Russell Brain (1952) writes " High blood-pressure causes paroxysmal, throbbing, or ' bursting ' headaches," and Platt (1950) asserts that " true hypertensive headache may be frontal or occipital and is usually most prominent in the early morning " Alexander (1948), in common with many other writers, has drawn attention to a parallel with migraine

Symonds (1946), however, contents himself with the more cautious statement that " headache is a common but inconstant symptom of arterial hypertension," while making the reservation that he is excluding from consideration the " relatively rare condition known as hypertensive encephalopathy " Wood (1950a) goes further and declares roundly that " it is doubtful whether any symptoms can be ascribed to high blood pressure itself " Others have agreed with this view

It was in an attempt to clarify this association between high blood pressure and the symptoms that so often accompany it that the following clinical study was undertaken Particular attention was paid to the significance of headache

Scheme of Investigation

The study was made upon 200 consecutive cases of severe hypertension and upon a number of controls All the patients were interviewed and examined by me Among the hypertensives the only criterion of selection was the height of the diastolic blood-pressure The standard adopted was a minimum of 120 mm Hg, measured with the patient recumbent, after ten minutes' rest in that position Whenever a reading had been made previously by another observer, the level then noted had nearly always been considerably higher than that obtained by this routine technique Occasionally the pressure was found at a subsequent examination to have fallen below 120 mm Hg Unless there had been obvious cause for this—e g , intervening cardiac infarction—all record of the patient was expunged from the survey It was thought best to abide by the blood-pressure alone as a standard for inclusion in the series Inevitably, however, this led to the omission of a few patients who, though clearly severely hypertensive, never presented a sufficiently high diastolic level, because when they were first seen, they had cardiac failure, recent infarction, or some similar complication

The following points were determined

(1) Whether or not the patient was aware of the raised blood pressure

(2) The volunteered symptoms, if any, in the order in which they were volunteered

which was used to some extent as a guide to effective dosage. At necropsy there was enlargement of the liver with marked fatty change in the mid-zones and, to a certain extent, the peripheral zones. No increase in glycogen was observed in histological preparations of the liver.

In five weanling rats which are being used for the first passage of a human tumour the two cortisone-treated animals bearing subcutaneous transplants weigh 10 and 11 g. at twelve days as against the 32 g. of each of the three controls. In the absence of distinct infection in the mice or the transplants this inhibition of growth is presumably due to depression of the pituitary by the cortisone.

THE CLIMBING OF EVEREST

SIR,—In connection with your annotation last week, one of the most interesting features of Colonel Hunt's account (*Times*, June 12) was the fact that three out of the five Sherpas chosen to do the final carrying at high altitudes were unable to, owing to altitude sickness, and that, in fact, much of the ultimate carrying over 27,000 feet was done by Europeans of the expedition. The courage and tenacity of the Sherpas as a group cannot be doubted, and their opportunities for acclimatisation one would assume to be greater than the Europeans'. Colonel Hunt's account therefore leaves us with a most interesting problem of the fundamental causes of high altitude sickness.

St. George's Hospital Medical School,
London, S.W.1.
NICHOLAS MARTIN.

JUNIOR RESIDENT STAFF

SIR,—We were disappointed in the letters which have appeared in your recent issues, commenting on our article of May 23.

Can we make it clear at the outset that we attempted to look at this problem from a national point of view and made an effort to put forward suggestions which in our opinion may ease the situation ? The observations made by your correspondents were only on limited aspects of the problem: they pin-pointed weaknesses without putting forward suggestions to improve the position.

To deal with the three points raised by "Filius Terræ" (June 6):

(*a*) "Cheap labour and no more." Is it not reasonable to expect that a graduate obtaining a teaching hospital appointment would be prepared to make a small monetary sacrifice as compared with the training facilities in a peripheral hospital? Is it not also fair to point out that newly qualified doctors working in hospitals are trainees not remunerated *according* to value of service, since they are gaining experience and some are trainee specialists ?

(*b*) Inducements of accommodation and facilities are no substitute for instruction and opportunity. Here we venture to suggest it should be the aim of all hospital managements to give resident medical staff the best possible accommodation and facilities, without in any way detracting from the value of supervision, instruction, and opportunity for self-improvement.

(*c*) After reading the quoted article by the committee of the American Medical Association on "The Essentials of an Approved Internship," we cannot accept the view that the training of doctors comes before the care of the patients. The two must proceed side by side.

We accept entirely the first point made by Dr. J. Greenwood Wilson—that working conditions in industry have to some extent permeated the hospital service. We regret that the old idea of a vocation is slowly passing. We compliment Dr. Greenwood Wilson on his outlook but must remind him that conditions have changed substantially since the days of which he speaks.

We can assure "Ex-House-officer" that in this area there is no lack of understanding of the junior medical officers' side of the problem: the consultants and the administration do everything in their power to assist house-officers in every possible way. "Ex-House-officer," we hope, does appreciate that certain regulations must be observed by everybody in a well-run organisation, but we can only assume that his experience has been unfortunate in connection with petty restrictions. When he implies there is no shortage of doctors for hospitals, he presumably shares the view of Mr. F. R. Zadik who in his letter of May 23 refers to a maldistribution of doctors; and it would have been helpful to hear how "Ex-House-officer" would have solved this problem.

We like Mr. Zadik's suggestions (May 23), although we feel there is a definite place for general practitioners in the hospital service as clinical assistants, even where a continuous emergency service is required. In this connection, we would point out that there are several acute general hospitals in this country with busy casualty departments where no house-officers are employed and where excellent service is given by general practitioners.

We only wish that consideration could be given to the employment of registrars at non-teaching hospitals as suggested by Mr. Zadik, and the possibility of introducing a new category of S.H.M.O. casualty officer could be investigated.

Replying to Dr. C. D. Needham (June 13), we would say that most of the junior housemen of our experience have completed twelve months' hospital service before entering upon their service with the Forces. This we believe to be general; so Dr. Needham's point upon the effect of service in the Forces would not be the great influencing factor he suggests. His statistical data are interesting and we note that the Medical Register has increased by some 27,000 names in nineteen years, a yearly average of about 1420, the average number during the last six years being approximately 1270, showing a definite falling off in the latter years. While we disagree with some of Dr. Needham's statements, we support wholeheartedly his view that it is high time that the medical man-power position be investigated as a comprehensive whole.

Dr. Needham asks: "Are lay administrators really the right people to advise on these matters ?" We are not seeking to advise: we are only seeking to focus a spotlight on an increasingly serious problem which has shown no improvement with the passing of each year of life of the "National Sickness Service." The hospital administrator must view the hospital service in all its branches, of which the medical services (though most important) form but one part. Our suggestions were simply meant to offer possible lines of inquiry, not advice.

Dr. Needham points out that barely half of the 83,914 registered doctors are occupying permanent established medical posts. If he could give us details of the disposition of the other half we might find ourselves much nearer to getting over our difficulties.

Finally may we reiterate that the junior medical staffing of hospitals is a national problem which needs early attention by all concerned if a partial breakdown in the service is to be avoided. If teaching hospitals and certain favoured peripheral hospitals have no problem, we suggest that they should come to the rescue of the less fortunate hospitals.

We have been most impressed by last week's article on this subject by Dr. R. M. Forrester and hope it receives the consideration it deserves. We hope to give it detailed study and would welcome an opportunity of offering further comment at a later date.

Wigan and Leigh
Hospital Group.

(3) The presence or absence of headache, whether volunteered or elicited.

(4) The nature of any headache admitted—in particular, its site and distribution, how long suffered in its present form, any previous migraine or tendency to have been a "headachy person," whether the pain was tending to get better or worse, its character, its duration, any precipitating or relieving factor, any history of past head injury, and any other possible cause of headache apart from hypertension.

(5) The patient's age on first interview, age on identification as hypertensive, present blood-pressure, cardiac rhythm, retinal appearances, electrocardiograms, and left ventricular size estimated radioscopically.

In pursuing these inquiries care was taken to avoid suggestion. Many patients began at once, early in the first consultation, to talk spontaneously of their "blood-pressure." If they did so, the subject was at this stage brushed aside. Instead they were asked what had first induced them to visit their own doctor, and whether they had now any symptoms. Later the blood-pressure was taken. At this point, if the patient had so far said nothing to show that he was already aware of his condition, his attention would be drawn to the sphygmomanometer. As if the aim were to make conversation, a casual question would be put asking whether he had "ever seen one of these things before." Sometimes the answer would be crisply to the effect that he had seen one only too often, ever since they had found out about his "blood-pressure." On the other hand, there might be no flash of recognition, the reply coming only in vague terms such as "Isn't it the thing you take blood-pressures with?" Exchanges of this kind invariably provided the clue to the patient's knowledge or ignorance of his hypertension without telling him anything, and without, apparently, evoking his curiosity.

A similar care was exercised in seeking to elicit the symptom of headache if it were not volunteered. Thus, for instance, the only spontaneous complaint might be of pain in the chest. If nothing more were forthcoming, there would then be addressed to the patient some such seemingly routine question as this: "You're all right in every other way, I suppose—no reason why you shouldn't be. You've not lost any weight? No cough? Or headache? No pains in the legs?" If the word "headache" were seized on, that was taken as evidence of the presence of this symptom on elicitation. Before its acceptance as significant it was further pointed out that of course, everyone gets headaches from time to time, the present concern was only with something definite.

Findings

Of the 200 hypertensives 93 were men and 107 women. The average diastolic pressure of the whole series was 136 mm Hg. All but 5 were in normal rhythm. Headache was volunteered by 57 patients, with men and women in about equal proportion; two thirds of these women were of menopausal age. The average diastolic pressure of all those volunteering headache was 145·5 mm Hg. From a further 31 patients the symptom was elicited. Thus the total number of patients laying claim to headache was 88, leaving 112 unaffected in this way. Further investigation was made into factors which, it was thought, might throw light on the relationship between such headache, or its absence, and the hypertension.

SEVERITY OF HYPERTENSION

The standards of severity adopted were four—the height of the diastolic pressure, the retinal appearances judged by the grading of Keith et al. (1939), the electrocardiograms, and the size of the left ventricle estimated on radioscopy. The interpretations that may be put on abnormalities presenting in these last two investigations are of course often highly debatable. In this survey only unequivocal electrocardiographic changes, for which hypertensive "strain" seemed overwhelmingly the most likely cause, were accepted as significant.

TABLE I—RELATION BETWEEN PRESENCE OF HEADACHE AND SEVERITY OF HYPERTENSION

Category	No of patients	Average diastolic B P (mm Hg)	E C G indications of L V strain	Fundi of hypertensive grade II or more	Hypertensive L V change on radioscopy
Headache	88	140·8	52%	51%	78%
No headache	112	133·6	69%	36%	60%

Patients with and without headache were compared (see table I). This shows that the average diastolic pressures of the two main groups were fairly close to each other, being respectively 140·8 and 133·6 mm Hg. In both groups the scatter was wide. Thus 3 of the 4 highest values in the whole series, all higher than 180 mm Hg, were found in patients who would admit to no headache. Of the other indications of severity radioscopic enlargement of the left ventricle favoured the group with headache, although not very much. By contrast electrocardiographic changes were seen slightly more often in the group with no headache. These differences were insignificant. Relative diminution in the calibre of the retinal arteries did, however, show an apparently significant tendency to be more severe in the patients with headache—51% against 36%. Moreover, as Pickering (1942) has found, the diastolic pressure tended to be highest among the patients with papillœdema—the criterion of so-called "malignant" disease. There were 18 such patients. Their average diastolic pressure was 159 mm Hg. Of these, 11 had headache. Apart from this it was at once evident that the severity of the hypertension gave no indication as to whether or not any individual patient might complain of headache.

TABLE II—RELATION OF HEADACHE TO KNOWLEDGE OF HYPERTENSION WITHIN PARALLEL GROUPS OF DIASTOLIC PRESSURE

HOSPITAL COSTING

SIR,—I pay tribute to Dr. A. F. Mohun's thoughtful article of May 16 upon hospital costing and its importance to the doctor. Few better services could be rendered to the cause of hospital efficiency than that of introducing the aims of departmental accounting to those from whom stem the specific application of most hospital activities. Much of the sage advice he gives—for example, on the vital importance of distributing the costs of "overhead" services—epitomises the findings of the three reports to which he refers. As further supporting comment upon these matters of common-agreement would be superfluous, I shall, if I may, draw attention to those features of the article which are, in my opinion, serious and even dangerous weaknesses.

The assiduity with which Dr. Mohun has so obviously analysed and dissected the theory of his subject unfortunately leaves him unaware not only of the lessons of practical accounting but also of the important psychological advantages that can flow from purposeful accounting in terms of individual responsibility.

By over-simplified examples, and by insistence upon probing the ultimate meaning of such accepted phrases as "objective accounting" and "subjective accounting," he leads himself to an unwitting yet fundamental contradiction. "My object in writing this article is to provide a corrective to any too-enthusiastic adoption of detailed schemes," he says (an object incidentally, which is at variance with the title of his article), and yet he advocates an approach to a scheme which in practice would involve hospitals in accounting intricacies of unlimited dimensions. It is easy to give a statement with six subjective and four objective headings, but it is fatally superficial to deduce therefrom that all that is involved in costing is "an extension of the present analysis." Regional treasurers insist upon more than forty subjective headings! Combine these by "extension" to each of the many departments of a hospital and to groups of hospitals, and we have a book-keeper's paradise but an accountant's nightmare. These practical accounting issues, part and parcel of an accountant's training and judgment, must inevitably influence such theorising, and an intensive programme of weeding out those innumerable accounts of no significance is clearly vital to the success of any scheme of costing. Failure to do so will assuredly prove Dr. Mohun correct in his opinion that a costing system "will itself cost money," just as it will confound the contrary view of those who have actually practised sensible departmental accounting. If only your contributor had drawn deeper upon his source of business accounting experience, he would have found that to accent the objective classification of expenditure does amount to a fresh outlook; and that one of the biggest obstacles that had to be overcome in business was the nostalgia for detailed expense classification by type.

His article deserves a much more intensive study of the many fields entered upon, but I must content myself with comment on just three other points.

An interesting contribution is made on the subject of statistical statements, but the suggestion that these should be adapted to varying needs of the several tiers of administration would have carried more weight if the individual hospital—still the only natural unity in hospital practice—had been accorded even a mere mention. Actual samples of such graded statements are given in the reports of the Nuffield Trust and the King's Fund, but neither body would legislate on this but would rather leave their selection to the independent judgment and requirements of each hospital.

The section of the article devoted to the "limitations of the costing system" turns out to be a somewhat platitudinous general warning against the misuse of costing material—no doubt much needed, but also applicable to almost every instrument used by human beings. A rather naïve example of this abuse of costs is left as though the fallacy arises from the costing system itself, whereas it derives from the clumsy application of a cost, produced for a particular purpose, to an entirely different set of circumstances in which a marginal cost was obviously required.

Finally, I consider it to be most regrettable that, in an otherwise excellent article, the author should summarise with the cliché of "the wholesale application of an elaborate conventional costing system." Without specific explanation, such phrases are meaningless; being negative, they are even more dangerous than the "slogans" against which Dr. Mohun warns his readers. It is to be devoutly hoped that in the practice of his own professional arts he does not allow himself to be fobbed off with inferior equipment—a child's spyglass, for example, in lieu of his microscope! Moreover, that he does not insist upon using the wrong end for fear of otherwise being thought conventional, and that essential lenses are not discarded merely to avoid the charge of being a "whole-hogger."

ADMINISTRATOR.

CATION-EXCHANGE RESINS

SIR,—I read with interest your leading article last week.

With diets low in Na the amount of Na taken up by a sulphonated exchange resin is low—less than 1 m.eq. per g. of resin.[1] We have now confirmed that the uptake of K is inversely related to that of Na; with diets low in Na it exceeds 2 m.eq. per g. Even if the resin is given partly in the K form, K may be removed from the body, and there is a danger of K depletion.

Department of Experimental Medicine,
Tennis Court Road, Cambridge.

PAUL FOURMAN.

THE EXPERT WITNESS

SIR,—Dr. Wells (May 30) raises a point of the utmost importance, subversive as it is of the whole principle of British justice.

Common Law in England is based upon the experience of some thousand years, and on the integrity and common sense of the layman. The McNaughten rules are objected to by psychiatrists because they take no account of emotional disturbance. The provision of a panel of psychiatrists, or of a single *amicus curiæ*, to assist the court in assessing the emotional factor, might have far-reaching effects. Obviously, any, to the layman, "sane" person who commits a crime is suffering from emotional disturbance, and to take this into account would ultimately lead to the acquittal of any person accused of any illegal act.

In a volume of the Notable British Trials series (*The Trial of John George Haigh*), the editor, Lord Dunboyne, who has achieved a masterly introduction, nevertheless falls into error in stating (p. 41) that the McNaughten Rules are the yardstick determining whether capital punishment shall be inflicted. This is not the case. The protection of the insane person is a defence in depth. The first line of defence is entrenched in the McNaughten rules, by which it must be shown that the accused was, at the time of the crime, suffering from such a defect of reason due to disease of the mind either that he did not know what he was doing, or that he did not know that it was wrong. Surely this is a fair decision for a jury of laymen. Having decided this point, there is yet another line of defence, which is best illustrated in the case of Ronald True.

There was no doubt that True was insane; his defence of insanity failed because it was equally obvious that he knew what he was doing at the time he committed the murder, and there was evidence to show that he knew that it was wrong. However, the defence having been one of insanity, the Home Secretary was, by statute provided, forced to appoint a committee of specialists to decide on True's sanity. This committee came to the conclusion that True was insane, and execution was therefore respited.

This is a sensible compromise, removing nothing from the jurisdiction of the Court, but preventing the inhumanity

KNOWLEDGE OF HYPERTENSION

Of the 88 patients with headache 71 (81%) were aware of their raised blood-pressure, whereas of the 112 patients who had no headache only 25 (22%) realised that their blood-pressure was in question, many of them had been sent to the outpatient department because of some complaint unconnected with the cardiovascular system Since there was no great difference in the average severity of disease between those with headache and those without it, this definite tendency of headache to appear more often among those aware of their condition might be taken to suggest that such knowledge had predisposed to headache Cause and effect could not be directly demonstrated, but there appeared a correspondence which might be significant Such a suggestion must be modified by the admission that a few patients in the survey maintained that they had learnt of their hypertension only after visiting their family doctor because of headache It was, of course, impossible to judge such a story with accuracy On close questioning, however it seemed unlikely that more than a very few of these people had, in fact, originally sought advice because of unexplained headache

TABLE III—ANALYSIS OF SYMPTOMS OF 25 PATIENTS WITHOUT HEADACHE THOUGH AWARE OF HYPERTENSION

Organic symptoms with hypertensive association	No of cases	Organic symptoms of unassociated disease	No of cases	Symptoms coupled with ' blood pressure " and suggesting anxiety	No of cases	No symptoms	No of cases
Anginal pain	5	Symptoms associated with carcinoma	4	Dizziness,' &c	1	No symptoms	1
Cardiac asthma	1	Melæna (peptic ulcer)	1	" Nerves " &c	1		
Visual difficulties	3			" Weakness, ' &c	1		
Effort dyspnœa	3			' Fainting attacks " &c	1		
" Fits " (hypertensive encephalopathy)	1			' Stuffed-up feelings ' &c	1		
				" Heart bulging out ' &c	1		
Total	13		5		6		1

Investigation from the opposite standpoint precluded exposure to this type of error (table II) There were 96 patients who were aware of their hypertension Of these, 71 (74%) complained of headache Yet of the 104 patients who did not know of their raised blood-pressure only 3 (less than 3%) volunteered that they had headache The symptom was elicited from a further 14 (bringing the total to 16%), of whom 12 were women, about half of them of menopausal age The remaining 87 (84%) denied headache These 87 were all, nevertheless, severely hypertensive Their average diastolic pressure was 135 mm Hg—only a millimetre less than the mean for the whole series Electrocardiograms suggesting left ventricular " strain " were found in 77% of them, and in 56% radioscopy revealed left ventricular enlargement Again the retinal damage was relatively less, being of grade II or more severity in only 27%

The relation between headache and knowledge of hypertension within parallel groups of diastolic pressure is demonstrated in table II The tendency of headache to appear in conjunction with knowledge of hypertension persists uniformly through the whole range By contrast, among patients unaware of their hypertension the paucity of headache is striking In this group the numbers tail off symmetrically upwards through the pressure gradient This accords with the casual pick-up of an abnormality occurring on a correspondingly diminishing scale of frequency On the other hand, most of the patients aware of their hypertension were regular attendants at a cardiological outpatient clinic, they thus formed a selected hypertensive sample of the population

Patients without Headache though Aware of Hypertension

The 25 out of 96 patients who escaped headache, though aware of their hypertension, did not do so because of any relative sparing of their cardiovascular systems Analysed separately the average diastolic pressure of these patients was 140 mm Hg, retinal changes of grade II or more were found in 52%, electrocardiographic changes of left ventricular strain in 89%, and radioscopic left ventricular enlargement in 92%—findings which indicate a severity well above the average for the whole series

All the same these patients, though aware of their hypertension, did not complain of headache At first sight this fact might be taken as evidence against any view that the symptom, when found among hypertensives, is commonly psychogenic

To investigate this point the case histories of these 25 patients were examined in detail They fell into four groups (table III)

(1) Patients whose attention was centred on some disorder which could be recognised as associated organically with the hypertension—e g, anginal pain or visual difficulties for which good cause could be found in the fundi

(2) The victims of severe incidental disease usually malignant The people in these two groups did not attach any importance to their blood-pressure, they had something else to worry about

(3) Mostly women whose symptoms, and the manner of their expression, suggested anxiety They complained of " weakness " or " blackouts " or " dizziness " which was neither rotatory nor related to posture They referred repeatedly to their " blood pressure " The impression was gained that these patients, knowing their blood pressure to be raised, found themselves afflicted by symptoms which they subconsciously felt to be appropriate to that disorder While others might seize upon ' headache " they, quite unwittingly, chose something else

(4) One stalwart avowed that he felt perfectly fit

Thus, of 96 hypertensives aware of their condition 71 complained of headache, 18 complained, with abundant organic justification, of something else, 6 produced symptoms which bore all the hallmarks of anxiety, and only 1 pronounced himself fit

Patients with Headache but Unaware of Hypertension

It seemed that a characteristic " hypertensive headache," if indeed such a thing should exist, might certainly be expected to show itself among the patients who complained of headache, without other evident cause, while unaware of their hypertension It has been pointed out that only 17 of 104 came into this category, a mere 3 complaining of headache spontaneously The severity of the hypertension affecting these 17, estimated by the usual criteria, was comparatively slight, with an average diastolic pressure of only 131 mm Hg, this being well below the average for the series Retinal changes of grade II were found in only 3, while less than half showed minor electrocardiographic and radioscopic abnormalities

The ages showed a wide scatter Nevertheless all members of the group were suffering much the same sort of headache Three-quarters of them had first noticed it within the previous three years, about half of them within eighteen months Most of them declared that the trouble had been bad but was now getting better They did not make a great deal of it Only 1 gave a history of previous migraine The pain was usually referred to one part of the head—front, back, or either side It might simulate migraine both in this localisation and in its liability to be precipitated by worry, activity, or excitement But there was never an aura The sensation might be described as " thumping," " bumping," or " bursting," the periodicity thus suggested being sometimes related to the pulse rate Transient faintness might accompany it Several patients confined their description to " just an ache " It was often at its worst in the early of the execution of an insane person, because, as Sir Edward Coke said, it lies beyond conscience to execute a man who cannot make his peace with God.

I have diffidence in penning this letter as I am neither a psychiatrist nor a barrister. As a member of the medical profession who has been interested in matters criminous for some time, I feel it my duty to express the frank opinion of one who has no axe to grind.

The confusion in the lay mind, and apparently among many psychiatrists, concerning the function of these two lines of defence seems to have caused unnecessary concern. The liberty of the subject, in the first instance in England, and ultimately, we may hope, in the whole world, depends upon the integrity of British Law. Any attempt to alter the existing constitution of our Courts of Criminal Law by the introduction of psychological advisors, financial advisors, political agents, or what-have-you is bound, sooner or later, to react with profound detriment to mankind. Unfortunately, no system is absolutely perfect, but hard cases make bad law. The McNaughten Rules and the provision for the respiting of an insane, but guilty, person provide an admirable compromise, and the public can remain assured that with such a system in operation injustice will be done in the minimal number of cases.

Newcastle upon Tyne. M. H. ARMSTRONG DAVISON.

ERYTHEMA MULTIFORME AND A.C.T.H.

SIR,—The cases of Stevens-Johnson syndrome treated with A.C.T.H., reported by Dr. Caldwell and by myself (June 6), strongly suggest that this condition is allergic in origin. Antibiotics definitely appear to be ineffective and may even be dangerous at times owing to monilial infection.[1]

Various cases supporting an allergic ætiology have been reported.

Ashby and Lazar[2] reported a case where the patient developed angioneurotic œdema following aspirin therapy, but they favoured an infective agent as the cause of this syndrome. Straus[3] and Thomas[4] both described patients who relapsed after the administration of sulphonamides; and a history of asthma or eczema has been reported.[5]

When A.C.T.H. is given, aureomycin should be given also as a prophylactic measure to prevent secondary infection of the skin lesions due to the lowering of the body's resistance by the action of A.C.T.H.[6]

Dr. Caldwell suggests that the use of A.C.T.H. in further cases of Stevens-Johnson syndrome would give a clearer picture of its value. I have seen 2 cases treated with A.C.T.H., and the accompanying photographs show the boy described in my letter. The lips are characteristic of erythema multiforme (fig. 1); œdema of the forehead and chemosis is predominant, and a diffuse coalescent maculopapular rash can be seen on the legs (fig. 2). He was completely cured with A.C.T.H. and aureomycin. In all, 6 cases have been reported in which A.C.T.H. has been used, and excellent responses have been noted. The search for an infective agent has proved negative,[7] and I think that the syndrome is definitely allergic in origin, sensitisation playing an important part.

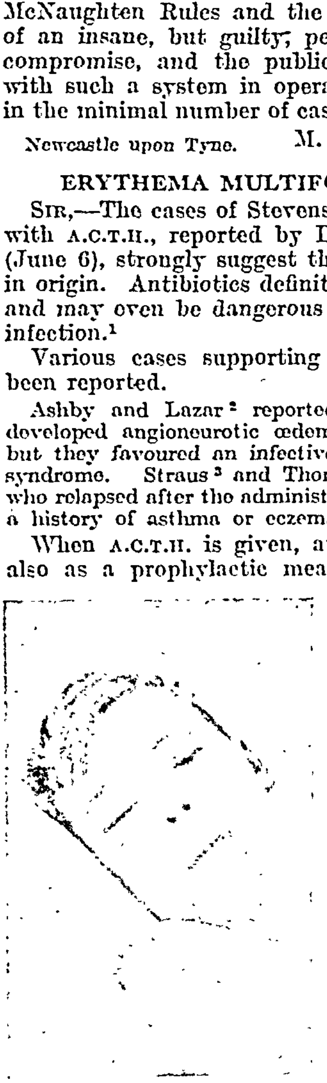

Fig. 1—Boy, aged 9, with Stevens-Johnson syndrome.

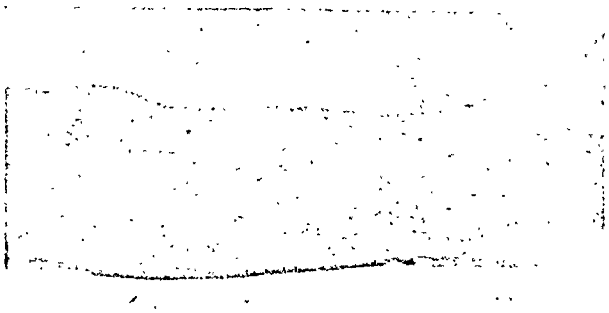

Fig. 2—Maculopapular rash on legs.

Whittington Hospital,
London, N.19. DEREK H. CLARK.

SIR,—Severe cases of erythema multiforme (Stevens-Johnson syndrome) are not common enough for controlled trials of treatment to be easily possible, but I feel that, since the condition is a self-limiting one, a very critical approach to therapeutic successes should be adopted. Of the four cases recorded in your issue of June 6, Dr. Davies makes no claim that his case recovered as a result of treatment; but Dr. Caldwell, Dr. Grant, and Dr. Clark ascribe recovery in their cases to the treatment used. Dr. Stephen Gold[8] has recently drawn attention to this uncritical attitude in respect of another case.[9]

I have perhaps seen more than my fair share of these cases, and in 1947 described six.[10] All these cases recovered completely in under four weeks, and a dramatic improvement took place 7–10 days from the onset of the illness. Dr. Caldwell's and Dr. Clark's patients did not begin treatment with A.C.T.H. until at least 6 days after the onset, and though it is quite likely that the beneficial response to treatment was a result of the treatment it is also possible that a natural remission was due to occur.

Most large centres will deal with two or three such cases a year, and it would appear practicable to treat every other case with A.C.T.H. early in the illness and to treat the remainder with antibiotics. Within a few years sufficient data would be gathered to settle this problem.

Rupert Hallam Department of
Dermatology, Royal Infirmary, Sheffield. I. B. SNEDDON.

TREATMENT OF HEPATIC COMA

SIR,—In your leading article of June 6 you cite a paper by Karl et al.[11] The implication of your remarks is that their 58 cases were treated on the regimen they recommend and despite this only 1 survived.

I read the paper differently, though my first interpretation was the same as yours.

To quote: "58 cases of cirrhosis complicated by hepatic coma were selected from the records of the St. Louis City Hospital. All but one of the patients had died. *Nearly* all had been observed by one of us." (*N.B.*, past tense.) The authors do not say how many years were covered by the series, though this is likely to be several and is important. They then survey the mode of presentation and pathological findings.

Under the heading "Management" they state that, because of the poor results in these cases "it seemed desirable to review the treatment used, and to search the literature for any theoretical or clinical studies that might suggest better methods of therapy." They go on to list the types of treatment but do *not* state how many of their patients had all or some of this treatment. The rest of the paper is a review of reports on the various therapeutic measures that have been used. There is little original contribution or critical

(3) The presence or absence of headache, whether volunteered or elicited.

(4) The nature of any headache admitted—in particular, its site and distribution, how long suffered in its present form, any previous migraine or tendency to have been a "headachy person," whether the pain was tending to get better or worse, its character, its duration, any precipitating or relieving factor, any history of past head injury, and any other possible cause of headache apart from hypertension.

(5) The patient's age on first interview, age on identification as hypertensive, present blood pressure, cardiac rhythm, retinal appearances, electrocardiograms, and left ventricular size estimated radioscopically.

In pursuing these inquiries care was taken to avoid suggestion. Many patients began at once, early in the first consultation, to talk spontaneously of their "blood-pressure." If they did so, the subject was at this stage brushed aside. Instead they were asked what had first induced them to visit their own doctor, and whether they had now any symptoms. Later the blood pressure was taken. At this point if the patient had so far said nothing to show that he was already aware of his condition, his attention would be drawn to the sphygmomanometer. As if the aim were to make conversation, a casual question would be put asking whether he had "ever seen one of these things before." Sometimes the answer would be crisply to the effect that he had seen one only too often, ever since they had found out about his "blood pressure." On the other hand, there might be no flash of recognition, the reply coming only in vague terms such as "Isn't it the thing you take blood-pressures with?" Exchanges of this kind invariably provided the clue to the patient's knowledge or ignorance of his hypertension without telling him anything, and without, apparently, evoking his curiosity.

A similar care was exercised in seeking to elicit the symptom of headache if it were not volunteered. Thus, for instance, the only spontaneous complaint might be of pain in the chest. If nothing more were forthcoming, there would then be addressed to the patient some such seemingly routine question as this: "You're all right in every other way, I suppose—no reason why you shouldn't be. You've not lost any weight? No cough? Or headache? No pains in the legs?" If the word "headache" were seized on, that was taken as evidence of the presence of this symptom on elicitation. Before its acceptance as significant it was further pointed out that, of course, everyone gets headaches from time to time, the present concern was only with something definite.

Findings

Of the 200 hypertensives 93 were men and 107 women. The average diastolic pressure of the whole series was 136 mm Hg. All but 5 were in normal rhythm. Headache was volunteered by 57 patients, with men and women in about equal proportion; two-thirds of these women were of menopausal age. The average diastolic pressure of all those volunteering headache was 145·5 mm Hg. From a further 31 patients the symptom was elicited. Thus the total number of patients laying claim to headache was 88, leaving 112 unaffected in this way. Further investigation was made into factors which, it was thought, might throw light on the relationship between such headache, or its absence, and the hypertension.

SEVERITY OF HYPERTENSION

The standards of severity adopted were four—the height of the diastolic pressure, the retinal appearances judged by the grading of Keith et al. (1939), the electrocardiograms, and the size of the left ventricle estimated on radioscopy. The interpretations that may be put on abnormalities presenting in these last two investigations are of course often highly debatable. In this survey only unequivocal electrocardiographic changes, for which hypertensive "strain" seemed overwhelmingly the most likely cause, were accepted as significant.

TABLE I—RELATION BETWEEN PRESENCE OF HEADACHE AND SEVERITY OF HYPERTENSION

Category	No. of patients	Average diastolic B.P. (mm Hg)	E.C.G. indications of L.V. strain	Fundi of hypertensive grade II or more	Hypertensive L.V. change on radioscopy
Headache	88	140·8	52%	51%	78%
No headache	112	133·6	69%	36%	60%

Patients with and without headache were compared (see table I). This shows that the average diastolic pressures of the two main groups were fairly close to each other, being respectively 140·8 and 133·6 mm Hg. In both groups the scatter was wide. Thus 3 of the 4 highest values in the whole series, all higher than 180 mm Hg, were found in patients who would admit to no headache. Of the other indications of severity radioscopic enlargement of the left ventricle favoured the group with headache, although not very much. By contrast electrocardiographic changes were seen slightly more often in the group with no headache. These differences were insignificant. Relative diminution in the calibre of the retinal arteries did, however, show an apparently significant tendency to be more severe in the patients with headache—51% against 36%. Moreover, as Pickering (1942) has found, the diastolic pressure tended to be highest among the patients with papillœdema—the criterion of so called "malignant" disease. There were 18 such patients. Their average diastolic pressure was 159 mm Hg. Of these, 11 had headache. Apart from this it was at once evident that the severity of the hypertension gave no indication as to whether or not any individual patient might complain of headache.

TABLE II—RELATION OF HEADACHE TO KNOWLEDGE OF HYPERTENSION WITHIN PARALLEL GROUPS OF DIASTOLIC PRESSURE

observation in this section; probably neither was intended. As a result of this review they then suggest a suitable regimen to follow in the future. There is no suggestion that it was in fact tried in their 58 cases.

I draw attention to what is, I think, a misinterpretation in your leading article as it may mislead readers to conclude that it is useless to treat hepatic coma from cirrhosis by any of the present methods. Indeed, this may be true, but this paper does nothing to prove it.

Ipswich. J. W. PAULLEY.

HEALTH OF A TROPICAL PEOPLE

SIR,—At the end of his interesting article last week Dr. Cullumbine gave a list of so-called diseases of civilisation.

The meaning of the word civilisation may be differently interpreted, but, as regards disease, it falls roughly into two eras: before and after the introduction of public health in general and of environmental and personal hygiene in particular.

People living in England, for example, in the reign of Queen Elizabeth I, paid their penalties for an over-indulgence in meat. An amount equal perhaps to about ten weeks of our ration might be scoffed at one meal! At a cost of what? About 2*d.*! They suffered from surfeit diseases and not inconsiderably, too, from their treatment. They suffered far more, though, from lack of sanitation, plague, and infectious diseases; and scabies was, I believe, almost universal. But circulatory and respiratory diseases are not particularly noted. In those days amenities were few, aids or replacements were few, and the average person had to use his body and his limbs to get about, to work, and to get his food—though they moved less, no doubt, than our more remote ancestors.

In this middle period of the 20th century, in the reign of Queen Elizabeth II, we enjoy immeasurable benefits from public-health services. On the other hand, owing to a vast increase in amenities, a large number of people are scarcely using their bodies at all and spend the day and evening sitting, standing, and being carried, while at work their bodies and limbs are being steadily replaced by machines. Surely a penalty is being paid in the silting up of the body tissues, varying in degree and in the site of manifestation. Shall we say diseases of "disuse"?

A failure of adaptation is now regarded as a starting-point for a number of functional failures leading to structural changes. Adaptation is mainly, however, a protective policy of living matter with which the human being has been trying to catch up, maybe ever since he stood directly upright. But the factors involved are largely beyond individual control. Disuse of the body should be open to correction.

London, W.1. F. D. SANER.

HAZARD OF FOG

SIR,—Although the Meuse Valley fog episode in 1930 appears to have been the first epidemic fog incident recorded,[1] the hazard of fog to sufferers from chest diseases was apparently well known as long ago as the 18th century. Thomas Percival, M.D., in his report to the Manchester Board of Health in 1796 refers to the problem thus:

> "I have computed that three hundred tons of coal are every day consumed in the winter season at Manchester. The factitious gas generated by its combustion must amount at least to one-third of this quantity; it is probable that the smoke proceeding from it constitutes another third part, and both together are capable of occupying a space of very wide extent. Now if it were not for the dispersion of these vapours by wind, the precipitation of them by rain, and the influence of other causes, which restore salubrity to the air, respiration could not be carried on under such circumstances. And we may observe that frosty weather, which is generally serene and without wind, always proves extremely oppressive, and sometimes even fatal to asthmatic patients in great cities. Indeed the rate of human mortality bears a pretty near proportion to their magnitude and population."

It is therefore particularly fitting that the centre of Manchester is one of the first places to be declared a smokeless area.

Windsor, Berks. ROBERT PIPER.

THE INCONTINENT WOMAN PATIENT

SIR,—I read with interest Dr. Brocklehurst's letter last week. Retention of a patient immobile over a receptacle offends against nursing principles; and I should like to recommend a different approach to the problem of the incontinent patient.

I look after a psycho-geriatric unit of 320 beds for frail patients over 70 years. There are no bedridden patients. The helpless ones are dressed and placed in sling armchairs built to retain an inert patient in a sitting position. The helpless, from a sitting position, watch and join in the social life of the ward. The sitting position prevents bedsores and pulmonary congestion, and patients can feed themselves much more readily.

There are 38 incontinent patients. These are dressed in towelling nappies and waterproof knickers to prevent soiling of furniture and clothing. Their cleanliness is ensured with mobility; the weak patients can be exercised, and the helpless ones can be dressed warmly. Urine rashes do not occur any more frequently. The saving in laundry and nurses' time is enormous.

No patient needs to be retained in bed because of mental apathy or paralysis.

Anyone with a young baby will be amazed that this idea has not been generally adopted.

Middlewood Hospital,
Sheffield.

G. I. TEWFIK
Assistant psychiatrist.

TREATMENT OF WHOOPING-COUGH WITH ANTIBIOTICS

SIR,—It is with diffidence that I offer criticism of the findings of the M.R.C. subcommittee which evaluated the effectiveness of chloramphenicol and aureomycin in the treatment of whooping-cough. Having been interested in the use and abuse of chloramphenicol particularly in relation to dosage, I feel impelled to offer a few comments.

In the subcommittee's trial reported in your issue of June 6, the drug was given twice a day in equally divided doses. I assume that the time-interval was 12 hours; and approximately 85% of an ingested amount of chloramphenicol is excreted during this period.[1] It can thus be reasonably argued that as the cumulative effect is minimal the therapeutic action depends on the amount given in this single 12-hourly dose.

Instead of treating each patient on the basis of tissue mass the subcommittee have chosen age. This adds to the difficulty in determining the amount given per kg. body-weight. By assuming, however, that the children were all mesomorphs (which is unlikely) and relating weight to age, the following would appear to be the approximate amount of chloramphenicol given per kg. per dose: 6 months, 65 mg.; 9 months, 55 mg.; 11 months, 50 mg.; 1 year, 75 mg.; 18 months, 65 mg.; 2 years, 62·5 mg.; $2^{1}/_{2}$ years, 55 mg.; 2 years 11 months, 52·5 mg.; 3 years, 70 mg.; $3^{1}/_{2}$ years, 65 mg.; 4 years, 60 mg.; $4^{1}/_{2}$ years, 57 mg.; 5 years 11 months, 55 mg.

For the assessment of results the cases were grouped into three categories and two divisions: early, middle, and late and severe or mild. The cases were partitioned without relation to age, and therefore weight. It would thus appear that no allowance was made for the possible effect of varying dosage levels in any given group, nor for the possibility that the groups might be unbalanced because the chance distribution of weights was erratic. Alternatively, the subcommittee may have

KNOWLEDGE OF HYPERTENSION

Of the 88 patients with headache 71 (81%) were aware of their raised blood-pressure, whereas of the 112 patients who had no headache only 25 (22%) realised that their blood pressure was in question, many of them had been sent to the outpatient department because of some complaint unconnected with the cardiovascular system Since there was no great difference in the average severity of disease between those with headache and those without it, this definite tendency of headache to appear more often among those aware of their condition might be taken to suggest that such knowledge had predisposed to headache Cause and effect could not be directly demonstrated, but there appeared [illegible] which might be significant Such a [illegible] modified by the admission that a few patients in the survey maintained that they had learnt of their hypertension only after visiting their family doctor because of headache It was, of course, impossible to judge such a story with accuracy On close questioning, however, it seemed unlikely that more than a very few of these people had, in fact, originally sought advice because of unexplained headache.

TABLE III—ANALYSIS OF SYMPTOMS OF 25 PATIENTS WITHOUT HEADACHE THOUGH AWARE OF HYPERTENSION

Organic symptoms with hypertensive association	No of cases	Organic symptoms of unassociated disease	No of cases	Symptoms coupled with "blood pressure" and suggesting anxiety	No of cases	No symptoms	No of cases
Anginal pain	5	Symptoms associated with carcinoma	4	'Dizziness,' &c	1	No symptoms	1
Cardiac asthma	1	Melæna (peptic ulcer)	1	"Nerves," &c	1		
Visual difficulties	3			"Weakness," &c	1		
Effort dyspnœa	3			'Fainting attacks," &c	1		
"Fits" (hypertensive encephalopathy)	1			'Stuffed-up feelings" &c	1		
				"Heart bulging out' &c	1		
Total	13		5		6		1

Investigation from the opposite standpoint precluded exposure to this type of error (table II) There were 96 patients who were aware of their hypertension Of these, 71 (74%) complained of headache Yet of the 104 patients who did not know of their raised blood-pressure only 3 (less than 3%) volunteered that they had headache The symptom was elicited from a further 14 (bringing the total to 16%), of whom 12 were women, about half of them of menopausal age The remaining 87 (84%) denied headache These 87 were all, nevertheless, severely hypertensive Their average diastolic pressure was 135 mm Hg—only a millimetre less than the mean for the whole series Electrocardiograms suggesting left ventricular "strain" were found in 77% of them, and in 56% radioscopy revealed left ventricular enlargement Again the retinal damage was relatively less, being of grade II or more severity in only 27%.

The relation between headache and knowledge of hypertension within parallel groups of diastolic pressure is demonstrated in table II The tendency of headache to appear in conjunction with knowledge of hypertension persists uniformly through the whole range By contrast, among patients unaware of their hypertension the paucity of headache is striking In this group the numbers tail off symmetrically upwards through the pressure gradient This accords with the casual pick-up of an abnormality occurring on a correspondingly diminishing scale of frequency On the other hand, most of the patients aware of their hypertension were regular attendants at a cardiological outpatient clinic, they thus formed a selected hypertensive sample of the population

Patients without Headache though Aware of Hypertension

The 25 out of 96 patients who escaped headache, though aware of their hypertension, did not do so because of any relative sparing of their cardiovascular systems Analysed separately the average diastolic pressure of these patients was 140 mm Hg, retinal changes of grade II or more were found in 52%, electrocardiographic changes of left ventricular strain in 89%, and radioscopic left ventricular enlargement in 92%—findings which indicate a severity well above the average for the whole series

All the same these patients, though aware of their hypertension, did not complain of headache At first sight this fact might be taken as evidence against any view that the symptom, when found among hypertensives, is commonly psychogenic

To investigate this point the case histories of these 25 patients were examined in detail They fell into four groups (table III)

(1) Patients whose attention was centred on some disorder which could be recognised as *associated organically with the* hypertension—e g, anginal pain, or visual difficulties for which good cause could be found in the fundi

(2) The victims of severe incidental disease, usually malignant The people in these two groups did not attach any importance to their blood pressure, they had something else to worry about

(3) Mostly women whose symptoms, and the manner of their expression, suggested anxiety They complained of 'weakness," or 'blackouts," or "dizziness" which was neither rotatory nor related to posture They referred *repeatedly to their "blood pressure"* The impression was gained that these patients, knowing their blood pressure to be raised, found themselves afflicted by symptoms which they subconsciously felt to be appropriate to that disorder While others might seize upon 'headache" they, quite unwittingly, chose something else

(4) One stalwart avowed that he felt perfectly fit

Thus, of 96 hypertensives aware of their condition 71 complained of headache, 18 complained, with abundant organic justification, of something else, 6 produced symptoms which bore all the hallmarks of anxiety, and only 1 pronounced himself fit

Patients with Headache but Unaware of Hypertension

It seemed that a characteristic "hypertensive headache," if indeed such a thing should exist, might certainly be expected to show itself among the patients who complained of headache, without other evident cause, while unaware of their hypertension It has been pointed out that only 17 of 104 came into this category, a mere 3 [illegible] headache spontaneously The severity [illegible] affecting these 17, estimated by the usual criteria, was comparatively slight, *with an average* diastolic pressure of only 131 mm Hg, this being well below the average for the series Retinal changes of grade II were found in only 3, while less than half showed minor electrocardiographic and radioscopic abnormalities

The ages showed a wide scatter Nevertheless all members of the group were suffering much the same sort of headache Three quarters of them had first noticed it within the previous three years, *about half of them* within eighteen months Most of them declared that the *trouble had been bad* but was now getting better They did not make a great deal of it Only 1 gave a history of previous migraine The pain was usually referred to one part of the head—*front*, back, or either side It might simulate migraine both in this localisation and in its liability to be precipitated by worry, activity, or excitement But there was never an aura The sensation might be described as "thumping," "bumping," or "bursting," the periodicity thus suggested being sometimes related to the pulse-rate Transient faintness might accompany it Several patients confined their description to "just an ache" It was often at its worst in the early decided that a dose-spread of approximately 20 mg. per kg. body-weight was of little experimental importance.

To me, there are three dominant factors to be considered in evaluating the effect of an antibiotic dose: the resistance of the organism, the patency of the vascular tree supplying the tissue under treatment, and the concentration of the antibacterial substance achieved per unit of pathological tissue. The acquisition of some knowledge of the first two is not difficult, but as far as I can determine there is very little known of the last. With this question in mind I have been collecting suitable necropsy material over the last eighteen months and subjecting it to chloramphenicol estimations, with some surprising results:

Case 1.—Weight 1·9 kg. Dose 50 mg. per kg. body-weight every 3 hours; last dose given about 4 hours before death.

Concentration of chloramphenicol per g. wet-weight lung tissue = 7μ.

Concentration of chloramphenicol per g. wet-weight brain tissue = 30μ.

Case 2.—Weight 2 kg. Dose 50 mg. per kg. body-weight every 6 hours. Last dose given 3 hours before death.

Concentration of chloramphenicol per g. wet-weight lung tissue = $7{\cdot}7\mu$.

Concentration of chloramphenicol per g. wet-weight brain tissue = $19{\cdot}8\mu$.

Case 3.—Weight 2·3 kg. Dose 50 mg. per kg. body-weight every 4 hours. Last dose given 50 minutes before death.

Concentration of chloramphenicol per g. wet-weight lung tissue = 12μ.

Concentration of chloramphenicol per g. wet-weight brain tissue = $2{\cdot}2\mu$.

This child died of widespread thromboses of the cerebro-vascular tree.

These three cases demonstrate that: (1) at any given time the chloramphenicol concentration varies from tissue to tissue; (2) vascular obstruction coincides with very low amounts of antibiotic; and (3) in the uninflamed human lung chloramphenicol is removed with some rapidity.

We know that *Hæmophilus pertussis* is markedly sensitive to chloramphenicol, but what we do not yet know is the amount of antibiotic that must be given in order to produce an optimum concentration in the diseased tracheobronchial mucosa invaded by this organism. It is obvious from what has been said that the various stages of the illness will require increasing dosages of chloramphenicol to bring about the same effects.

This thesis cannot be fully expanded within the confines of a letter, but I feel that its substance suggests that it would have been advisable for the subcommittee to have qualified their findings by relating them only to the dosage system tried.

London, S.W.9.

J. D. GRAY.

Public Health

World-wide Poliomyelitis

POLIOMYELITIS was often described in the past as a disease of temperate climates; but *nowadays* there is good evidence to show that few parts of the world are free from poliomyelitis viruses. Indeed, one view is that they originated in the tropics.[1] The World Health Organisation has now published[2] a survey of the attacks made by the disease during 1952, and the figures from 113 countries and territories show how widespread they were. In North America there was more poliomyelitis than ever before: in the United States more than 57,000 *cases* were *notified*—twice as many as in 1951 and more than in any year since notification began: and in Canada the number of notifications for both August and September exceeded the annual totals for the majority of the preceding 28 years. "A veritable wave" spread over Europe, involving particularly Denmark, Western Germany, and Belgium. Provisional figures for England and Wales show an increase from 3095 cases in 1951 to 4475 in 1952; but, the report observes, "the notifications do not show such a regular and, one might almost say, inexorable tendency to rise during the last 20 years as is the case in the United States." On the other side of the world, there was a serious new outbreak in New Zealand, the Hawaiian Islands, and the Gilbert and Ellice Islands; but in Australia and Japan the number of cases reported showed a definite decrease. And 1952 was also quite a good year in Africa, where recorded cases fell by 25%, though in Kenya and Tanganyika "notifications exceeded all figures recorded since 1945." For the fourth time since 1934, there was a sharp outbreak in the island of Mauritius. As the report points out, the total number of notifications from tropical countries is still low, but there are relatively few doctors to detect the disease in these areas, and the indication is that poliomyelitis "remains or is becoming a threat of world-wide significance."

Obituary

GEORGE WILLIAM RIPPON

M.B. Sheff.

Dr. Rippon, consultant anæsthetist to the United Sheffield Hospitals, died on June 1 in Sheffield, where he had spent the whole of his medical career from student to consultant. After graduating as M.B. at the University in 1925 he held house-appointments at the Royal Infirmary and the Jessop Hospital before settling in general practice at Abbeydale. As the years passed his growing interest in anæsthetics absorbed more and more of his time and finally led to his appointment to the staff of the United Sheffield Hospitals.

R. P. writes: "George Rippon was an exceptionally good doctor; indeed, it was difficult to see patients with him, for he always knew so much more about them and their illnesses than the consultant whose advice he appeared to be seeking, and there was always the likelihood that a sudden devastating comment from George, uttered in the kindest and gentlest of tones, would come dangerously near to upsetting any dignity or solemnity which had been assumed for the occasion. He had wit and erudition and his friends all had a warm affection for him as well as a great respect for his judgment. I should guess that he had no enemies, for his comments on the pompous and self-opinionated were framed in terms which they would not comprehend. I know few men who come anywhere near to his standards of doctoring and it is the greatest pity that we should lose him so soon. Nevertheless I find it almost impossible to feel solemn about George. He just wouldn't like it."

Dr. Rippon leaves his widow with a son and two daughters.

Appointments

ARRATOON, LILY, M.R.C.S., M.R.C.O.G.: asst. M.O., child health and maternity services, West Ham.

BENNETT, P. A., M.B. Brist.: principal M.O. (mental health service), Middlesex County Council.

CLARK, A. S., M.B. Lond., D.P.M.: psychiatrist, public-health department, London County Council.

GLANCY, B. P., M.B. Belf., D.P.M.: psychiatrist (S.H.M.O.): Northern Ireland Hospitals Authority special care service.

GRAY, I. G., M.B. Lond.: appointed factory doctor, Acle, Norfolk.

JACKSON, C. R. S., M.A., B.M. Oxfd, F.R.C.S.E.: asst. ophthalmic surgeon, Edinburgh Royal Infirmary.

LUDLOW, JOYCE, M.B.E., M.B. Lond., F.R.C.S.: asst. county M.O., N.E. Kent area.

MURPHY, J. H., M.D. Dubl.: appointed factory doctor, Biddulph, Staffordshire.

morning; this, however, was by no means constant or predictable. When it was severe, nothing short of complete rest and analgesics would relieve it.

MALIGNANT HYPERTENSION

There were 18 patients who had entered the so-called "malignant" phase, in virtue of the development of papillœdema superimposed upon the primary retinal vascular changes. The average diastolic pressure was 159 mm. Hg. A detailed examination was made of this group. To 6 of them the nature of their illness remained unknown. Of these, only 1 complained of headache. On the other hand, 10 of the remaining 12, all aware of their hypertension, complained of this symptom. It thus seems possible that, even with this degree of hypertension, auto-suggestion may sometimes play a part in the production of headache. Again, about half of those who complained of it maintained that it was becoming less. None of them had previously experienced migraine. The average age at onset of the symptom was 40 in men and 33 in women.

The headache endured by these victims of malignant hypertension proved recognisable as a fairly clear-cut entity. It had never been present for long. Very commonly it was referred to one eye, often to the "back" of an eye, or it might be described in terms such as a "pulling of the eye." In addition there might be episodes of transient impairment of vision in addition to a recent progressive deterioration. Usually it was unilateral. It might affect any part of the head. It was often described as "thumping" or "bursting," but again it was evident that these sensations did not always bear a relation to the pulse-rate. Sometimes the pain, for so long as it was present, was "continual." It seldom lasted for more than a few hours at a time. Perhaps its most constant feature was its association with nausea, if not with vomiting. It was evident that to these patients the headache was only a part, and it might be a relatively trivial part, of their affliction. Rarely did it dominate and absorb them, as so often happens with the headache of a space-occupying intracranial lesion. Even without the complications of congestive failure, pulmonary œdema, or uræmia, these unfortunate people felt wretched in a way which they found difficult to define. "I just feel thoroughly miserable" was an expression several times heard. Two of the patients in this "malignant" group might have been said to be experiencing "hypertensive encephalopathy" in that spasmodic headache was accompanied on occasion by transient palsies or by fading of consciousness.

FACTOR OF ANXIETY

It has been pointed out that 104 of the patients in this survey did not know that their blood-pressure was abnormal. Of these 87 would admit no headache. On the other hand, all but one of those who had learnt of their condition offered symptoms of some kind, those with headache numbering 71 out of 96. These headaches, however, were seldom described in terms bearing any resemblance to those used with a readily appreciable uniformity by the few patients who protested headache while ignorant of their disease. Obviously the fact that a patient may have discovered that he has hypertension gives him no exemption from any organic symptom which that disorder may induce. Yet in fact, most of these 71 patients gave the clear impression that their symptoms stemmed from anxiety consequent on that knowledge.

Those so affected included many elderly women. The ubiquitous 'blackout' figured prominently in their stories. 'Dizziness' was mentioned specifically by 23 of them; only 5 made this complaint while ignorant of their hypertension. Of the whole 200 no more than 4 or 5 had experienced true vertigo without evident cause in a labyrinth or elsewhere. It then seemed that such vertigo might have an organic origin in the cerebral cortex, analogous to that occasionally presenting in migraine. Usually, however, the complaint of dizziness did not suggest an organic basis.

The headaches of these 71 patients, it was at once evident, had nearly all begun soon after the victims had first learnt of their hypertension. The reality of the complaint was seldom in doubt; but it was described in terms characteristic of anxiety. Commonly it was said to be "continual," in the sense of never ceasing for a moment. Activity, nevertheless, or inert tablets might relieve it. Sometimes it was "bad in the morning." Above all it was evident that "headache" and "blood-pressure" were regarded as a virtually inseparable combination. One lady expressed it: "But I thought blood-pressure *was* headache." A second remarked, perhaps more significantly than she realised: "Before I knew I had this blood-pressure I didn't have any headaches." To all of them it seemed natural and indeed inevitable that, if their blood-pressure was raised, they must have headaches. Many of the people in this survey used the terms "blood-pressure" and "headache" as if they were interchangeable.

CONTROLS

Patients who had complained of headache without any evidence of organic illness were questioned. A neurologist (Dr. A. M. G. Campbell) had judged the background to be one of anxiety. These people often volunteered that their headaches were worse in the early morning. Such timing is, of course, also characteristic both of migraine and of space-occupying intracranial lesions. Moreover, transient indisposition of many kinds can produce, in otherwise normal people, a "hangover" type of morning headache. Such a sensation may, perhaps, become exaggerated, as part of a neurosis, and be experienced daily. Many of these controls complained also of "dizzy feelings." Their symptoms were, in fact, indistinguishable from those offered by most of those hypertensives who had headache while aware of their high blood-pressure.

A further 3 controls had complained incidentally of long-standing headache, for which no reason could be found, after admission to hospital for abdominal surgery. It was suggested to them that the surgical treatment would in all probability achieve the happy additional effect of curing this headache. Six months later all 3 declared their headaches to be much less severe.

Discussion and Conclusions

This survey seems to show that headache can result directly from hypertension. Such headache is rare, but it bears the stamp of an organic symptom. In character it closely resembles migraine. Reasonably, perhaps, it may be supposed that its origin is similar—that it is due, in fact, to intermittent stretch of the cerebral arterial walls, and is analogous to that produced experimentally with histamine by Pickering (1933), Graham and Wolff (1938), and others. Such is the view of Symonds (1946), who holds that a few of the headaches that accompany arterial hypertension appear to have "much the same basis as those of migraine."

On the other hand, it seems to be indisputable that in association with hypertension a second type of headache occurs very often. This headache derives from anxiety. Platt (1950) has said that "very many hypertensive subjects . . . have been given an anxiety neurosis by the discovery of their high blood-pressure. It would not be far from the truth to say that the majority of symptoms of hypertension are iatrogenic." The conclusion to be drawn from the present investigation reinforces that assertion. Supporting evidence was obtained from several sources. Thus of the 104 patients unaware of their hypertension only 3 volunteered that they had headache, a further 14 admitting it, the tendency for headache to be absent persisted symmetrically

Notes and News

RECIPROCAL SOCIAL INSURANCE

The Under-Secretary for Commonwealth Relations announced in the House of Commons last week that an agreement on social security between the Government of the United Kingdom and the government of Australia was signed by the Prime Minister and the prime minister of Australia on June 8. The agreement covered retirement pensions and widows' benefits, unemployment and sickness benefits, and family allowances on the United Kingdom side, and the corresponding benefits of the Australian social services scheme. It was hoped that the agreement would come into operation early next year; and the full text will be published shortly as a white paper.

A similar reciprocal agreement between the United Kingdom and Italy has now been brought into force.[1] The agreement covers retirement pensions, widows' benefits and guardian allowances, unemployment, sickness and maternity benefits, and all industrial injuries benefits. The agreement also provides for each country to take account of insurance contributions paid in the other country so that people who go from one country to the other will not lose their benefit rights. Employed persons who are sent to Italy by their employers in Great Britain for short periods will, in future, remain fully insured under the British National Insurance and Industrial Injuries schemes while in Italy.

University of Oxford

On June 6 the following degrees were conferred:

D.M.—R. R. de Mowbray, R. A. Sladden, E. M. Vaughan Williams.

University of Cambridge

Mr. H. U. Willink, master of Magdalene College, has been elected to the office of vice-chancellor for the academical year 1953–54, in succession to Sir Lionel Whitby.

On June 6 the following degrees were conferred:

M.D.—R. E. Church, *R. J. Dickson, H. G. Dowler, R. D. Eastham, J. W. Fawcett, John Foley, D. K. Ford, Gordon Wetherley-Mein, D. B. B. Whitehouse.

* By proxy.

University of London

The following have been successful in the examination for part I of the diploma in psychological medicine:

J. E. A. Bartlet, Valerie A. Cowie, L. A. Hersov, S. G. E. Laverty, I. J. MacDonald, A. A. Reid, M. J. Rosenthall.

University of Birmingham

The council has approved a recommendation that undergraduates of all faculties should be X-rayed at the beginning of each year of their course.

The title of reader in systematic bacteriology has been conferred on Dr. K. A. Bisset, lecturer in bacteriology; the title of reader in social medicine on Dr. R. G. Record, lecturer in social medicine; the title of honorary lecturer in radiology in the department of surgery on Dr. C. G. Teall, university clinical lecturer in radiology; the title of university research fellow on Dr. W. Taylor, part-time lecturer in medical statistics, during his tenure of a Rockefeller fellowship; and the title of university clinical lecturer on Dr. J. F. K. Hutton (radiology).

Professor C. H. Pae, of the department of pharmacology of the University of Taegu, South Korea, will work in the department of pharmacology for a year from Oct. 1, 1953.

The Barling scholarship, for postgraduate work in surgery, has been awarded for 1953 to J. M. Small, university clinical lecturer in neurosurgery.

University of Edinburgh

Dr. D. J. A. Kerr has been appointed to the regius chair of forensic medicine in succession to Sir Sydney Smith, who is retiring.

Dr. Kerr, who is 58, was educated at St. Paul's School, London, and Edinburgh University, where he is at present a lecturer in forensic medicine. He graduated M.B. in 1920, and took the D.P.H. two years later. After holding a resident post at the Fife and Kinross District Asylum he was appointed assistant pathologist to the Edinburgh Royal Infirmary. In 1927 he became F.R.C.P.E., and graduated M.D. with commendation. Since 1929 he has been police surgeon and medical referee to the City of Edinburgh. He sits on the General Medical Council as the representative of the Royal College of Physicians of Edinburgh. His textbook on *Forensic Medicine* first appeared in 1935 and is now in its fourth edition.

University of Glasgow

The diploma in public health has been awarded to the following:

G. G. Browning, Helen W. Greenlees, H. M. Macfarlane, Sheenah J. M. Russell, L. G. Samuel, Richard Short, R. S. Sloan, Elizabeth Stewart, Norval Watson.

Royal College of Surgeons of England

At a meeting of the council on June 11, with Sir Cecil Wakeley, the president, in the chair, the following were coöpted to the council for the year 1953–54 representing various branches of practice:

Dr. O. C. Carter (general practice), Prof. A. M. Claye (gynæcology and obstetrics), Mr. M. L. Formby (otolaryngology), Dr. B. R. M. Johnson (anæsthetics), Mr. A. B. Nutt (ophthalmology), Sir William Kelsey Fry (dental surgery).

The following examiners were appointed for the ensuing year:

[illegible] E. A. Blake Pritchard. Anatomy: Th [illegible] Mary F. Lucas Keene, Lambert Ro [illegible] and Pathology: D. T. Harris, Theodore Crawford, Geoffrey Hadfield, Albert Hemingway.

Diploma of L.R.C.P., M.R.C.S.—Elementary Biology: A. G. Hamilton, C. C. Hentschel. Anatomy: Thomas Nicol, E. W. T. Morris, A. J. Heriot. Physiology: C. C. N. Vass, Esther M. Killick. Midwifery: R. K. Bowes, D. M. Stern, R. G. Maliphant, W. R. Winterton. Pathology: Sir Ernest Finch, L. E. C. Norbury, Joseph Bamforth, A. C. Cunliffe.

Diploma in Public Health.—Preliminary: Arthur Massey. Final: Stanley King.

Diploma in Tropical Medicine and Hygiene.—P. C. C. Garnham, A. W. Woodruff.

Diploma in Ophthalmology.—R. C. Davenport, A. B. Nutt, T. Keith Lyle, A. G. Cross, A. M. Reid, Eugene Wolff, E. F. King.

Diploma in Psychological Medicine.—Part I: Louis Minski.

Diploma in Laryngology and Otology.—Part I: G. H. Livingstone, F. C. W. Capps. Part II: W. A. Mill.

Diploma in Medical Radio-Diagnosis.—Part I: F. W. Spiers. Part II: Hugh Davies.

Diploma in Medical Radiotherapy.—Part I: F. W. Spiers. Part II: J. A. C. Fleming.

Diploma in Child Health.—G. H. Macnab, D. F. Ellison Nash, W. F. Gaisford.

Diploma in Physical Medicine.—Part I: E. J. Crisp, Leon Gillis. Part II: Philip Wiles, W. S. Tegner.

Diploma in Industrial Health.—L. G. Norman.

Diploma in Pathology.—J. H. Dible, Theodore Crawford.

Diploma in Anæsthetics.—Surgery: C. E. Shattock. Anæsthetics: W. Alexander Low.

Mr. R. Danbury (Royal Free) was presented with the Begley prize.

Diplomas of fellowship were granted to the following:

R. L. Rees, D. G. B. Bennett, R. A. J. Baily, R. L. A. Gouges-d'Agincourt, J. R. Dyer, R. L. Batten, J. G. Kendall, †Robert Pracy, Geoffrey Mizbah, R. W. Povey, A. H. M. Littlewood, C. S. Kirkham, C. F. Noon, D. B. Leaming, P. W. Seargeant, D. C. Stevenson, E. C. Edwards, Phyllis A. George, D. B. J. Wardle, F. G. Ellis, E. A. Badoe, Fida Mohamad Khan, I. B. Speight, †Ben Cohen, *Brojo Mohan Chatterjee, Anil Krishna Barat, R. D. Venn, K. J. Watson, W. G. Davidson, Parimal Chandra Ghosh, E. O. Williams, D. S. Kidd, W. P. Crone, Ralph Ger, J. R. Kenyon, †F. D. Martinson, J. P. Swain, W. N. Coombes, *J. S. Groves, J. M. Mynors, Daphne M. Scott, *Jack Swartz, H. T. Thompson, Paul Abbey, H. H. Francis, *Irene D. R. Gregory, E. F. Shanahan, N. D. Ashe, H. J. Bagnall, †R. J. Bennett, Ram Prosad Chakrabarty, M. W. Falloon, J. M. Hay, Robert Jacobs, Allan Kelly, L. E. Neri, Jamnadas Narottam Ravalia, E. L. Angliss, Jean-Jacques Brossy, J. V. L. Colman, †D. F. Cossar, D. G. L. Davies, *R. F. Elliott, Dinshaw Jamshedji Ghadialy, J. K. Henderson, A. F. Hunter, Pearse O'Donoghue, O. E. Owen, *I. W. Payne, Philip Rhodes, Vasant Kanaiyalal Vani, A. J. C. Allison, J. K. Clarebrough, *R. H. L. Ferguson, †H. J. Groves, P. J. Heery, Joseph Jaconelli, Geoffrey Slaney, G. C. Slee, J. G. Watson, M. E. E. White, Ismail Ahmed Agjee, Nirmalchandra Rochiram Amesur, Muhammad Ismet Khurshid Anwar, G. B. Cavaye, Subir Kumar Chatterjee, J. A. Hanley, C. Q. Henriques, J. T. Hueston, G. J. Kane, P. A. King, E. R. McKenzie, C. P. Mills, J. K. M. Quartey, M. W. Reece, N. A. Stephens, C. H. Talbot, A. W. R. Williamson, R. E. Candlin, D. S. Cole, K. J. Coleman, R. D. Cundall, M. B. O'Donnell, D. A. Simpson, R. H. Thorlakson, W. J. D. Bradfield, B. S. Pearson, R. J. M. Whittle.

* In ophthalmology. † In otolaryngology.

Diplomas of membership were granted to G. P. Lowther and B. K. A. Muller.

Royal Medico-Psychological Association

The following have been successful in the association's examinations for the diploma in psychological medicine:

Part I.—R. E. Brandon, N. C. Connell, F. H. Corbitt, W. Johnston, R. E. Lovelace, J. Mukerjee, Elizabeth Shoenberg, D. C. V. Stewart.

Part II.—Ruth Hoffman, N. B. Jetmalani.

Medical Insurance Agency

At the annual meeting of the Medical Insurance Agency, held on June 11 with Dr. James Fenton in the chair, Sir John McNee, Mr. R. L. Newell, Dr. Henry Robinson, Sir Arnold Stott, and Dr. E. R. C. Walker were re-elected to the committee, and Dr. Janet Bottomley was elected for the first time. Dr. Fenton was re-elected as chairman and Dr. Robinson as secretary.

[1] The National Insurance and Industrial (Reciprocal Agreement with Italy) Order, 1953; S.I. 1953, no. 884. 6*d.*

through all grades of diastolic pressure Yet the symptom was complained of usually in terms strongly suggesting neurosis by 71 out of 96 comparable hypertensives who knew the nature of their illness It had then nearly always appeared shortly after their acquisition of that knowledge Moreover most of the 25 remaining out of this 96 had excellent organic cause for concentrating their attention on something else Only 1 declared himself to feel well On the strength of these findings it seemed virtually impossible for a patient to remain symptom-free after being told of his raised blood-pressure.

How are the organic and anxiety types of headache to be distinguished? Features which have been widely held to indicate typical "hypertensive" headache—e g exacerbation in the early morning—seem after all, to be of little diagnostic value There are however, better points of distinction, they are summarised in table IV

On the whole, the organic type of headache has seldom been present for more than a few months It declares itself soon after the pressure begins to rise either for the first time, or after a period of stability following an initial increase The severity of the hypertension, shown by the diastolic pressure and the state of the left ventricle, plays no direct part in its production. In the late stages however, there is a tendency for advanced retinal changes to be associated with it It is likely to resemble migraine in its unilateral localisation and in liability to be precipitated by worry or excitement, but there is no aura Transient faintness, occasionally true vertigo, may accompany it It seldom lasts for more than a few hours at a time While severe it responds only to complete rest or powerful analgesics After a time it tends to become less The victim is unlikely to be of more than middle age He is often unaware that his blood-pressure is in question

By contrast, the onset of the anxiety type of headache follows closely on the patient's first learning of his "blood-pressure". The sufferer may be beyond middle age, commonly an elderly woman Bizarre complaints, typical of anxiety, accompany the headache, which tends to be perpetual. Suggestion, however may bring relief

TABLE IV—COMPARISON OF FACTORS CHARACTERISTIC OF ORGANIC AND ANXIETY HEADACHE FOUND IN ASSOCIATION WITH HYPERTENSION

Organic	Anxiety
Rare	Common
Seldom found over middle-age in women often at menopause, sometimes much younger	Any age, common in the elderly, particularly women
Often no knowledge of disease	Always knowledge of "blood-pressure"
Short history of headache	Headache dates from the time of acquiring knowledge of 'blood pressure'
Severity of hypertension tends to be: (1) comparatively slight, or (2) malignant (state of left ventricle of no account)	Severity (measured by any standard) of no account
Retinal changes often severe in later stages of hypertension	Severe retinal changes relatively uncommon
Headache often "bad in the morning"	Headache often 'bad in the morning
Headache made worse by worry and activity	Headache made worse by worry, may be lessened by activity
Headache often tending to get less	Little spontaneous relief inert tablets may be effective
Headache like migraine, but no aura: vertigo occasionally faints more common, in malignant" phase eye pain, nausea and feeling of wretchedness	Headache bizarre typical of neurosis accompanied by or alternating with, black-outs' dizzy turns' &c, faints rare, no nausea no vertigo

Headache of the type which can be supposed organic was found in three main groups of hypertensives

(1) *Menopausal women* —Two-thirds of the women volunteering that they had headache were of menopausal age The symptom may be caused at this period of life by associated organic changes, which are probably vascular

(2) *With early benign hypertension* —The average severity of hypertension among the 17 patients who complained of headache while unaware of their hypertension was much below the average for the rest of the series Moreover three quarters of these patients had developed their headache comparatively recently, more than half of them declaring that there had already been considerable improvement Lovibond (1949) has suggested that headache may result, in hypertension, from the first rise in pressure

(3) *With malignant hypertension* —Such patients fall into a separate category, which has been described Deep eye pain, nausea, and severe general malaise are almost constant accompaniments of the headache.

These organic varieties of headache are rare Should they present in a menopausal woman, or in a patient whose blood-pressure has lately begun to rise, they can confidently be expected to vanish spontaneously particularly on rest, within an hour or two, and to exhibit a general tendency, over a longer period to disappear of their own accord It follows that successful treatment of organic headache caused by benign hypertension can never be identified with certainty In fact, whatever may be the evidence of success in combating this form of hypertension, the alleviation of headache can never, logically, be part of it

Nearly all the headaches presenting during the course of benign hypertension are due to anxiety They are thus likely to respond favourably to any form of treatment that promises benefit It has been shown by Friedman et al (1949) that the degree of the response is likely to vary directly with the impressiveness of the treatment adopted Sympathectomy seems to be well qualified in this respect

With malignant hypertension the problem is different In this condition organic headache presents fairly often, even if submerged among other symptoms Sympathectomy seems to be effective in reducing it It may be noted, however, that according to Wood (1950b) a mere 0 2% of persons with simple hypertension pass into the malignant phase

Today there is some hope of cutting short the sinister, and still unexplained rise in blood-pressure that occurs in hypertension In particular the new hypotensive drugs show promise Already it seems that on occasion, cardiac failure may be postponed visual difficulty improved. and life prolonged. The future is hopeful Yet it would be a pity if a confusion of premises should lead to false optimism Certainly it would be well to remain unimpressed with any measure that bases its claims upon the relief of headache.

Summary

A survey was made of 200 consecutive patients with severe hypertension The average diastolic pressure measured under standard conditions of rest, was 136 mm Hg

Assessment was made of the symptom of headache, whether spontaneous or elicited by an interrogation technique designed to avoid suggestion.

Those patients who were aware and those unaware of their hypertension were compared. The severity of disease was found to be roughly the same in the two groups estimated by diastolic level, electrocardiograms, and radioscopic appearances of the left ventricle Retinal changes were somewhat greater in those with headache

Of the 104 patients unaware of their hypertension 87 would not admit to having headache This tendency for headache to be absent persisted symmetrically through all grades of diastolic pressure The symptom was volunteered by only 3 of these patients, being elicited from the remaining 14 Of 96 patients

Faculty of Radiologists

The annual meeting of the faculty will open at the Royal College of Surgeons, London, at 9.30 A.M. on Friday, July 3, and will continue on July 4.

Lady Tata Trust

The trustees of this fund announce that they have made the following awards for research on leukæmia and allied diseases, in the year beginning next October:

Grants for research expenses or for scientific assistance.—Dr. Astrid Fagraeus and Dr. Bo Thorell (Stockholm); Dr. Clarence Merskey (Cape Town); Prof. Charles Oberling (Paris); Dr. C. C. Ungley (Newcastle upon Tyne); Dr. Jo Nordmann (Paris).

Part-time personal grant.—Dr. J. B. G. Dausset (Paris).

Scholarships.—Dr. Ragna Rask-Nielsen (Copenhagen); Dr. Roger Robineaux (Paris); Dr. Flemming Kissmeyer-Nielsen (Aarhus, Denmark); Dr. N. A. Stenderup (Aarhus, Denmark).

Senior Research fellowships.—Dr. A. R. Gopal-Ayengar (India) for work at the Royal Cancer Hospital; Dr. Jørgen Kieler (Denmark) for work at the Fibiger Laboratories, Copenhagen.

A special scholarship awarded to Dr. Gavino Negroni (Italy), for work at the Imperial Cancer Research Fund Laboratories, will continue until April 30, 1954.

Beit Fellowship for Medical Research

The following awards have been made:

Fourth-year Fellowship

JOAN E. KEILIN, M.A., M.B., PH.D. Camb. To investigate the catalytic activity of hæmatin compounds and the effect of oxidising agents on hæmatins. Also to investigate the properties of purified helicorubin and its relationship to other natural hæmoproteins; and to investigate the reactions of hæmatins with proteins and their constituent amino-acids and peptides to gain more information as to the structure of the hæmoglobin molecule and the link between the hæm and globin and to use hæmatin as a reagent for the study of other biologically important proteins. At the Department of Biochemistry, Cambridge.

Junior Fellowships

J. R. CANNON, M.SC., Sydney. To continue the study of the chemical structure of Vitamin B_{12}. At University Chemical Laboratories, Cambridge.

G. P. LEWIS, B.PHARM. Wales. To study the relationship between structure and action of drugs, particularly of antagonists of histamine, acetylcholine, adrenaline, and noradrenaline, to examine how far ionisation of a drug or its receptor modifies drug action. At the National Institute for Medical Research, Mill Hill, London.

W. L. NICHOLAS, B.SC. Lpool. To investigate the determination of the growth requirements of free-living and parasitic nematodes in chemically defined media, with a view to its possible application to the chemotherapy of nematode infections. At the Department of Zoology, Liverpool University.

EVELYN E. B. SMITH, B.SC., PH.D. Glasg. To investigate the enzymic mechanisms of transfer reactions involving uridine pyrophosphate compounds containing glucose, glucuronic acid, and N-acetylglucosamine; and the biosynthesis of glucuronic acid, glucuronides, and oligosaccharides containing glucuronic acid, *using carbon and phosphorus isotopes.* At the Department of Biochemistry, Glasgow University.

South Western Regional Hospital Board

The Minister of Health has appointed Sir Havergal Downes-Shaw, O.B.E., to be chairman of this board. Sir Havergal Downes-Shaw, a former departmental manager of the Imperial Tobacco Company, has been a member of Bristol City Council since 1931 and an alderman since 1946.

Society for Relief of Widows and Orphans of Medical Men

This society's annual meeting was held on June 10, with Sir Robert Young, the president, in the chair. Members of the society number 198; and at the end of 1952 there were 35 widows in receipt of grants. Widows over 65 receive £75, and those under that age £60 a year. In addition a present of £30 was made at Easter, and again at Michaelmas. The total amount distributed in 1952 was £4525. Sir Ernest Rock Carling, the treasurer, reported that during the year income exceeded expenditure by £723. The address of the society is 11, Chandos Street, London, W.1.

Institute on Œsophageal Speech

An institute on teaching and improving œsophageal speech will be held on Aug. 10–16 at the Cleveland Hearing and Speech Center, Cleveland, Ohio. This institute is being sponsored by the American Cancer Society, the National Cancer Institute of Institutes of Health, the Office of Vocational Rehabilitation, the Cleveland Otolaryngological Society, the Cleveland Academy of Medicine, and the Western Reserve University School of Medicine. Non-speaking laryngectomised persons may attend without charge. They may be sent by surgeons, cancer societies, societies for crippled persons, and rehabilitation services. Surgeons, speech pathologists, and laymen are also invited to attend the sessions. Application must be made by July 15 to Warren H. Gardner, PH.D., program chairman, 11206, Euclid Avenue, Cleveland 6, Ohio.

Royal Medical Benevolent Fund

At the annual meeting, held on June 9, honorary offi were re-elected as follows: president, Lord Webb-Johns treasurer, Mr. F. A. Juler; secretary, Dr. R. Cove-Smith.

International Hæmophilia Society

A meeting of this society is to be held at Seymour H London, W.1, on Sunday, June 21, at 2 P.M. The Lond Group will meet at the society's offices, 94, Southwark Brid Road, S.W.1, on Wednesday, July 1, at 6.30 P.M.

Visitor in Lunacy

The Lord Chancellor has appointed Dr. R. G. Anders a commissioner of the Board of Control, to be a medical visit in the place of Dr. A. E. Evans who is retiring.

Oxford Graduates Medical Club

The summer dinner will be held in the Queen's Colle Oxford, on Friday, July 10, at 7 for 7.30 P.M. Dr. C. G Douglas, F.R.S., will preside. Tickets (£2 2*s*. inclusive) ma be had before July 4 from Mr. Solwyn Taylor, F.R.C.S., 3 Roedean Crescent, London, S.W.15.

Diary of the Week

JUNE 21 TO 27

Monday, 22nd

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.1
4 P.M. Dr. W. Ritchie Russell: Poliomyelitis.

Tuesday, 23rd

SOCIETY FOR ENDOCRINOLOGY
5.30 P.M. (1, Wimpole Street, W.1.) Dr. Charles Hu (Chicago): Prostatic Glands as Targets for Steroids.

Wednesday, 24th

POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Dr. E. F. Gale: Mode of Action of Antibacterial Ag (First of two lectures.)
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Str W.C.2
5.30 P.M. Dr. H. Haber: Parapsoriasis, Poikiloderma Mycosis Fungoides.
BRITISH ASSOCIATION OF SPORT AND MEDICINE
5 P.M. (Westminster Hospital Medical School, Horsefer Road, S.W.1.) Sir Adolphe Abrahams, Dr. McEldowney: Doping of Athletes.
BIRMINGHAM MEDICAL INSTITUTE, 154, Great Charles Str Birmingham, 3
8 P.M. *Section of Psychiatry.* Dr. W. Mayer-Gross: Problem of t Symptomatic Psychoses.

Thursday, 25th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Prof. Arnold Sorsby: New Antibiotics.
UNIVERSITY COLLEGE, Gower Street, W.C.1
4.45 P.M. Prof. J. H. Quastel, D.SC., F.R.S. (Montreal): Acti of Drugs on Enzyme Systems.
POSTGRADUATE MEDICAL SCHOOL OF LONDON
4 P.M. Colonel W. R. M. Drew: Recent Advances in Malari Problems.
INSTITUTE OF CHILD HEALTH, The Hospital for Sick Childr Great Ormond Street, W.C.1
5 P.M. Dr. W. C. Davison (Duke University, North Carolina) Childhood Cancer.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. R. W. Riddell: Subcutaneous Mycotic Infectio
INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Roa W.C.1
5.30 P.M. Prof. B. Gusic (Zagreb): Pathological Change Blood-vessels and Nerves of Œsophagus Due to Corro
BRITISH ASSOCIATION OF UROLOGICAL SURGEONS HOME A OVERSEAS
11 A.M. (General Infirmary, Leeds.) Short papers.
2 P.M. Professor Huggins: Adrenal in Cancer.

Friday, 26th

POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Dr. C. E. Dent: Diagnosis of Hyper-parathyroidism.
4 P.M. Prof. L. J. Witts [illegible] Splenectomy.
INSTITUTE OF LARYNGOLOG [illegible]
3.30 P.M. Mr. Anthony [illegible]
BRITISH ASSOCIATION OF [illegible] HOME A OVERSEAS
9.30 A.M. Mr. J. Cosbie Ross, Mr. J. G. Gow, Dr. J. Colqu Mr. M. F. Nicholls: Urinary Tuberculosis.

Saturday, 27th

UNIVERSITY OF CAMBRIDGE
10.30 A.M. (Addenbrooke's Hospital, Cambridge.) Postgradu symposium on diseases of the ear, nose, and throat a diseases of the eye.
BRITISH ASSOCIATION OF UROLOGICAL SURGEONS HOME A OVERSEAS
9.30 A.M. Short papers and films.

aware of their hypertension 71 complained of headache, most of them in terms characteristic of anxiety On analysis of the remaining 25 it was found that 18 had good organic cause for complaining of something else, and 6 offered symptoms characteristic of anxiety

From these and other findings, together with evidence afforded by the examination of controls, it was concluded that the headache which so often accompanies hypertension is usually a product of anxiety Moreover it seems almost impossible for a patient who has been told of his "blood-pressure" to remain symptom-free

It appeared further that hypertension might occasionally produce headache as an organic symptom It was most likely to do so in menopausal women, during the early stages of benign hypertension, or, as a relatively insignificant feature, within the syndrome of malignant hypertension

Analysis was made of factors which serve to distinguish this rare organic headache from the common one which is due to anxiety

Attention is drawn to the fallacy of acclaiming any treatment of hypertension in virtue of its alleged cure of headache

This survey was made at the instigation, and with the advice, of Dr D H Davies Most of the patients concerned were under his care A few, however, were under the care of other members of the consultant staff of the Bristol Royal Infirmary, to whom, therefore, I should like to express my thanks

INTRA-ARTERIAL TRANSFUSION

THE POTASSIUM HAZARD

D G Melrose
B M Oxfd
ASSISTANT LECTURER

A O Wilson
B Sc, M B Edin
REGISTRAR

DEPARTMENT OF SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

The replacement of blood with the least possible delay is now regarded as fundamental in the prevention and treatment of shock Blood may be replaced rapidly either by the intravenous or the intra-arterial route The pros and cons of intra-arterial transfusion have been discussed by Seeley and Nelson (1952) in a review of most of the pertinent literature and it may be said that such transfusions can be a life-saving measure and are often the method of choice The extreme case of resuscitation of the clinically dead has been reported by Negovsky (1945) and Gold et al (1949) have reported dramatic results in patients with complete circulatory collapse

The mode of action of such transfusions seems to be that the intra-aortic pressure is rapidly raised to a level sufficient to revoke the intense vasoconstriction previously initiated by the pressoreceptors in the aortic arch and carotid sinus, and hence to promote restoration of normal vascular tone, which in turn permits normal perfusion of the capillary networks, particularly those of the heart and brain, which may even be perfused directly by the ingoing infusion

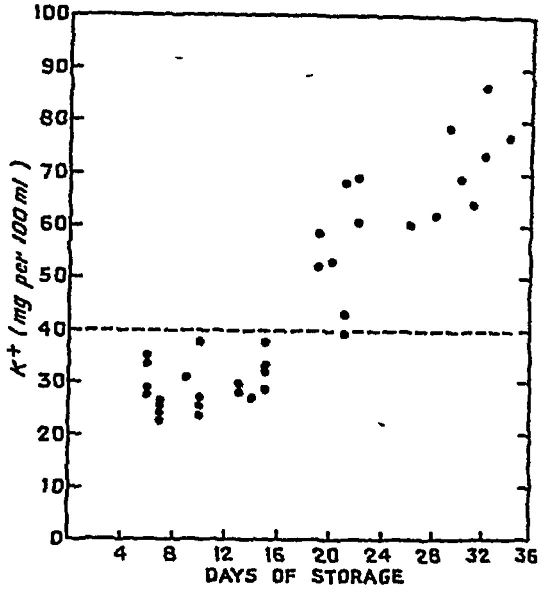

Fig 1—K+ values of samples from plasma-cell interface of bottled blood.

POTASSIUM IN STORED BLOOD

Intra-arterial transfusions are generally given in emergencies and often in large amounts, and therefore stored blood must usually, if not always, be used This raises the possibility of adverse effects due to the altered chemical composition of stored blood Crafoord (1948) expressed a preference for fresh blood when large amounts are to be given rapidly, but did not refer to the question of the chemical composition of the blood

Mainwaring et al (1940) and De Gowin et al (1940) have drawn attention to the rapid release of potassium from the red cells during the storage of blood, and we have confirmed their results (fig 1) Potassium was determined by means of an internal standard flame photometer based on that described by Berry et al (1946) Our figures tend to be lower, possibly because of improved methods of storage and because our samples were collected from the region of the plasma-cell interface Nevertheless plasma-potassium levels of 35 mg or more per 100 ml are not uncommon in blood stored for up to three weeks This figure of 35 mg of potassium per 100 ml of plasma is just below the fatal concentration in man, which is about 40 mg of potassium per 100 ml

The danger of giving potassium-containing solutions intravenously has been much emphasised (Fenn 1940, Hoffman 1950), and for administration by this route at a rate not exceeding 2 or 3 ml per minute a safe potassium concentration is about 200 mg per 100 ml (50 m eq per litre) This would be diluted to give a rise in plasma-potassium level of only about 0·25 mg per 100 ml (0·06 m eq per litre) per minute, provided the blood volume was normal and all the potassium remained in the plasma Wright (1952) states "The high plasma K+ concentration of stored blood must be borne in mind as K+ in excess has toxic effects on the circulation these may be avoided if the transfusion is performed at rates not exceeding 40 cc per minute"

In the same context Blixenkrone-Moller (1949) advises against the use of stored blood if many transfusions are to be given in quick succession, even by the intravenous r Law" (*British Medical Journal* 1909). This was view of doctors in private practice, and there were ications that at that time many of them would have n prepared to accept a salary for part-time public vice.

he full implementation of either of these proposals ght have prevented the division between the preventive d curative personal services. For the medical staff of gressive public-health authorities were then extenely engaged in treatment as well as prevention of sease, and had both been sanctioned by Parliament it n hardly be doubted that a unified service would have own up—no doubt with serious effects upon private actice. Alternatively, had general practitioners been rmitted to undertake the work in schools, and later child-welfare clinics, it is also possible that the division ight have been avoided. In this case the attitude of octors to local-authority administration and payment by lary might later have been different from what it was. he Education Act, 1907, and the Maternity and Child Velfare Act, 1918, effected a compromise, by assigng the preventive personal services to public-health uthorities, while curtailing treatment in deference to he wishes of private doctors. This in effect made revention a public responsibility, and left treatment a rivate one. The National Health Service Act removed his distinction, but left the machinery of administration f the personal health services essentially unchanged.

Against this background we turn to an examination f the work done at child-welfare clinics today, and to onsideration of their future organisation.

Material of Study

We collected our data by investigation of work done at child-welfare clinics in Birmingham (population 1,112,340), and Coseley (an urban district in the administrative county of Stafford, population 34,414).

In Coseley there is only one welfare centre, a well-equipped modern building designed for the purpose. School, antenatal, postnatal, and child-welfare clinics are held in this centre. There are no special sessions for toddlers, and the obstetrician responsible for the combined antenatal and postnatal clinics does not examine infants; consequently the child-welfare sessions, held twice a week, cater for preschool children of all ages. The medical officer who holds these clinics (J. T. A. G.) is also medical officer of health for Coseley. Two qualified health visitors attend each session.

In Birmingham, child-welfare clinics are held at 33 different centres. Of these, 2 (a church hall and a Friends' meeting-house) are in part-time use by the local authority; 31 are full-time child-welfare centres. Of the latter, 13 were designed and built as clinics; the remaining 18 originally served some other purpose (private residence, municipal house, public house) and were adapted by more or less extensive structural alterations for use as children's clinics. Some of these buildings are unsatisfactory, and but for building restrictions during and since the war would have been replaced.

In Coseley all child-welfare services, including immunisation against diphtheria, are provided at the same clinic session. In Birmingham, although all children under 5 years old may attend, the children's clinics are mainly concerned with the supervision of children between 3 and 18 months of age. Mothers with babies under 3 months are encouraged to attend special postnatal clinics, mothers with older children (18 months to 5 years) are given quarterly appointments for toddlers' clinics, and immunisation against diphtheria is offered at special immunisation sessions. The 33 welfare centres provide 64 children's clinics a week, and employ fifteen full-time and twenty-six part-time medical officers, of whom all but four are women. At each session two, occasionally three, health visitors are in attendance.

After a pilot survey conducted at Coseley two record cards were designed. The first was completed by a social worker, who interviewed mothers in reasonable privacy as they arrived at the clinic and recorded their reasons for attending on that particular day. The second card was completed in Coseley by the clinic medical officer (J. T. A. G.), and in Birmingham by one of two medical observers (J. T. A. G. or C. R. L.) who sat in with the clinic medical officer. Data recorded were: sex, age, and birth rank of each child; the reason for medical consultation; and the type of service or services given by the doctor. Direct questioning of the mother was usually unnecessary, since most of the information was available in clinic records or from the mother's conversation with the medical officer. The work of the health visitors at the clinics was not examined in detail.

In the pilot survey the health visitor recorded the reason for attendance at the clinic. This proved unsatisfactory, because health visitors were already fully occupied and because consultations were usually within earshot of those waiting. This part of the inquiry was therefore conducted by a social worker in Birmingham; it was omitted in Coseley.

The Coseley data were collected at 62 consecutive sessions at the child-welfare centre between the end of July, 1951, and the beginning of May, 1952; the Birmingham data were obtained by a single visit, between Feb. 11 and May 12, 1952, to a children's clinic at each of the city's 33 centres. At Coseley the same child was often seen at more than one attendance. In Birmingham, as the postnatal and toddler sessions were excluded, the material is weighted in favour of children between 3 and 18 months of age. Of children referred to medical officers, the proportions under 3 months were 48% and 17% in Coseley and Birmingham respectively. Neither of these features seriously affects the results of our analysis, which is concerned primarily with the work of the clinics and not with the children attending.

Results

REASONS FOR ATTENDING THE CLINIC

The reasons given for attending were to have the child weighed, to obtain advice from the health visitor or doctor on some specific problem, and to purchase proprietary foods (table I). On the recommendation of the medical officer proprietary foods are available at wholesale prices, and whatever the official view mothers evidently consider this function of the clinic important. Nearly half of them (44%) gave food purchase as a reason for attending, 19% gave it as the only reason, and 15% had not brought the child with them. (In principle mothers are not allowed to buy food unless the child has been seen within the preceding fortnight.) In addition, an average of 51 mothers per clinic session attended for the sole purpose of shopping at the branch food offices established at 26 of the 33 Birmingham centres. These mothers, who came without children, did not enter the clinic proper, and are excluded from all tables.

REASONS FOR REFERRING CHILDREN TO THE MEDICAL OFFICER

The proportions of children referred by health visitors to the medical officers were 39% and 27% in Birmingham and Coseley respectively (table II); the average numbers

TABLE I—REASONS GIVEN BY BIRMINGHAM MOTHERS FOR ATTENDING CLINIC

The traditional services provided by local health authorities were designed to meet circumstances which existed during the 19th and early 20th centuries, in particular the high incidence of infectious disease and the absence of a generally available personal medical service During recent years the incidence of infectious disease has been greatly reduced, and since 1948 personal medical attention has been provided through a national service Yet except for the transfer of hospitals to regional hospital boards, there has been no major change in the organisation of the local-authority services, some of which overlap the general-practitioner and consultant services, while others are unsatisfactorily separated from them A re examination of the work of local health authorities against the background of the National Health Service is clearly necessary, and it is the purpose of the present communication to consider the work done by the child-welfare clinics provided under schemes for maternity and child welfare

HISTORICAL BACKGROUND

The traditional child-welfare service consists essentially of four features

Food Distribution—The distribution of cheap and safe milk to women who could not breast-feed their babies was introduced in France and England at the end of the 19th century The service was later extended to include dietetic supplements, and a National dried milk scheme was added during the last war

Advisory Service—Systematic instruction of working-class mothers by women with some knowledge of hygiene began in Manchester in 1862 as a voluntary service In time it was taken over by local authorities, and trained nurses (health visitors) were appointed, whose primary duty was the education of the mother at home and in clinics on all matters related to the care of her child

Routine Examination—In response to widespread concern about the health of young people, systematic medical inspection of school-children was recommended in the report of the Inter-Departmental Committee on *Physical Deterioration of 1904*, and was provided fo the Education Act, 1907 Regular examination later included among services for the preschool cl but is even now irregularly applied many authori insist on only one medical examination (at the postn clinic, or at the first visit of the child to a welfare cent others aim at examinations at the 1st and 3rd birthda while in some cases an attempt is made to exan children at three-monthly intervals throughout presc life

Medical Service—Free medical attention was off at infant clinics in France at the end of the 19th cent and in England at the beginning of the 20th This ser originally comprised both prevention and treatmen disease, but treatment was later curtailed Neverthe a considerable amount of treatment, mainly of a m kind, is still given at the clinics

The child-welfare service of today is composed of t diverse elements They were derived in part from 19th-century environmental services, but resulted ma from extension of local authority interest to pers services which had formerly been the concern of poor-law authority and voluntary agencies T development was ultimately responsible for the separat of the preventive from the curative personal serv and the reasons for it are of considerable histor importance

Local authorities entered the field of personal he service because of the inadequacy of existing provis for the care of children, of which there was evidenc the high infant-mortality rate (154 in 1900), and high proportion of recruits considered unfit for milit service (40% in 1901–02) For those unable to for treatment, the alternatives at the beginning of century were the medical services of the poor law o voluntary agencies But although it was generally agr that some extension of the public service was nee and that the medical branch of the poor-law was unsatisfactory means of providing it, how it should administered was for many years in dispute Broadly may be said that there were two proposals, and service which eventually emerged was a comprom between them

The first was the proposal that there should be a unif State medical service, based on public health princip and organised in local areas This was recommend to the Royal Commission on the Poor Laws (1905–09) by the heads of the four Government medical depart ments, who undoubtedly expressed the views of mo doctors in the public service

The alternative proposal was that the additional public medical services should be given by doctors in private practice According to the medico political committee of the British Medical Association " the most satisfactory provision for the treatment of children whose parent cannot afford to pay for it is to place them under the care of private practitioners, who should be adequately remunerated out of public funds independently of th route. Trumper (1951) has made similar observations on the use of plasma obtained from stored blood in the treatment of burns, and our measurements of the potassium level in twelve samples of plasma withdrawn from 1000-donor pools (fig. 2) confirms that values above 40 mg. per 100 ml. are common. Trumper also drew attention to the fact that, in shock, oliguria and a decreased cardiac output obviously potentiate the effect of any increase in plasma-potassium level, and these same factors operate in the similar but smaller changes in cardiac output and renal function occurring in all surgical patients.

The danger to the patient is largely the effect on the cardiac musculature of too high a concentration of potassium. It *may* be that another determining factor operates—i.e., the rate at which the cells can take up the excess of circulating potassium. Nevertheless a raised plasma-potassium level produces extrasystoles and ultimately death from cardiac arrest in diastole (Best and Taylor 1950).

REDUCTION OF POTASSIUM LEVEL

Since stored blood may contain a high level of potassium, attempts were made to reduce this by various means, so as to make the blood safer for rapid and massive intra-arterial transfusion. Maizels (1949) reinvestigated Harris's (1941) observation that incubation of stored blood at 37°C for a few hours in the presence of glucose causes cation distribution to return to normal. He found, however, that potassium did not return to the cells until after eight hours, the pH and other factors being of great importance in determining the rate. Thus the ideal method of restoring the composition of the blood is unfortunately impracticable.

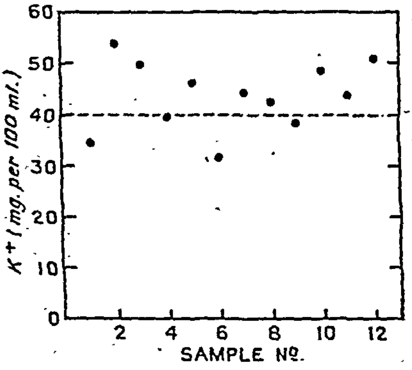

Fig. 2—K+ values of twelve samples of plasma from 1000-donor plasma pool.

Much of the potassium which has diffused out of the red cells may be removed by decanting the plasma from stored blood and reconstituting with physiological saline solution or better, with salt-free dextran, since this would obviate the risks attached to the administration of large amounts of sodium chloride to patients many of whom would be suffering from cardiac disease. It may be argued that this is inadequate since the plasma-potassium level round the sedimented red cells is higher than in the supernatant fluid. The volume of plasma remaining between the cells is, however, relatively small. This method proved to be a useful means of reducing the potassium level, a reduction of over 40% being obtained after replacement of the supernatant plasma by saline solution. Fig. 3 shows the reduction of potassium level in 13 samples of bank blood stored for more than twenty-one days. The cells and saline solution had been gently mixed and the potassium level determined on the "plasma" after centrifuging.

CARDIAC EFFECTS OF EXCESSIVE POTASSIUM

Attempts were also made to demonstrate in the dog the danger of intra-arterial transfusions of blood containing high levels of potassium by studying the effects of these on the electrocardiogram. Though slight changes were noted, no unequivocal evidence was obtained. Nevertheless these changes were probably significant in view of the fact that the fatal potassium level is higher in the dog than in man, and the total amount of potassium given was less than a quarter of that required by Winkler et al. (1938) to produce changes in the electrocardiogram after slow intravenous infusion.

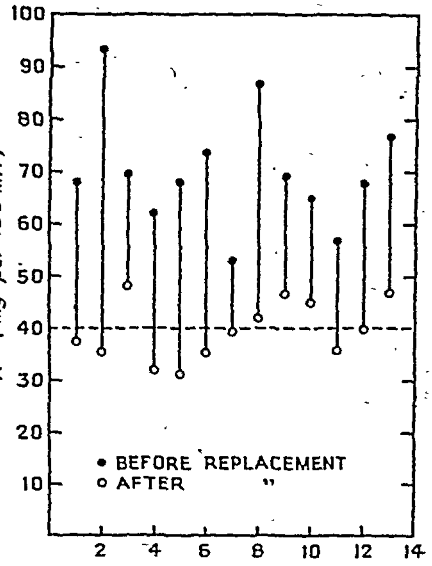

Fig. 3—K+ values of thirteen samples before and after replacement of plasma by isotonic saline solution.

Three important considerations govern the effect of potassium solutions, given intra-arterially on the heart. These are the direction of flow of the transfusion, the extent to which it is diluted in its passage to the heart, and the immediate state of potassium metabolism in the recipient. According to the site of infusion and the existing cardiac output, the bulk of the entering blood will go either with the normal stream away from the heart or in a retrograde direction into the coronary vessels. Where the output of the heart is very low a large proportion of the entering blood must go into the coronary vessels, regardless of the site of infusion, and in the stopped heart this undoubtedly happens (Smirenskaia and Maksimishina 1951). Jones et al. (1950) showed that 35% 'Diodrast' injected into the femoral artery of the dog passes directly into the coronary vessels if the systolic blood-pressure is less than 50 mm. Hg. It has further been demonstrated that, even in the presence of a normal cardiac output, the infused fluid may enter the coronary vessels if given into the aorta (Steiner 1952, Page 1946).

If mixing is instantaneous and complete, it is theoretically possible to give with safety a transfusion of 500 ml. of blood a minute, with a plasma-potassium level of as much as 100 mg. per 100 ml. (25·6 m.eq. per litre); for, even if the cardiac output is as low as 2 litres a minute, the level of potassium in the mixed blood reaching the heart should not exceed 36 mg. per 100 ml.—a safe level. In practice it is unlikely that mixing is complete and instantaneous, and the possibility exists that dangerous amounts of potassium may be *forced into* the heart although the output is not seriously reduced. In those instances where the output is less than 2 litres a minute, and it is under just such conditions that intra-arterial transfusions are particularly indicated, dilution may not reduce to a safe level the amount of potassium in the plasma of stored blood when this is given at an adequate rate. Especially is this likely in operations on the heart, where the output may temporarily fall to nil, and it must be assumed, and indeed is hoped, that the infused blood passes directly into the coronary vessels.

RESUSCITATION

In such circumstances it is essential to have available a simple method of resuscitation. Experience with a modified Henri-Jouvelet rotary pump suggests that it is the ideal device for rapid transfusion into either artery or vein. In use the tube connecting the blood reservoir of corticosteroids can be estimated without the usual unsatisfactory hydrolysis and extraction procedures

The term "17-ketogenic steroids" will be used here to denote corticosteroids bearing the side-chains III, IV, or V—i.e., those converted by bismuthate (and not by periodate) into 17-ketosteroids

Method

24 hour urine specimens are collected without preservative, made up to 2 litres with distilled water, and stored in a refrigerator Each specimen is assayed, in duplicate, concurrently for 17 ketosteroids (17-K.S.) and for "total 17 K.S." (after bismuthate oxidation) The difference between the two measurements represents the 17 ketosteroids formed from 17 ketogenic steroids on oxidation This figure is designated '17 K.G.S.' On a molar basis, and subject to the limitations inherent in the colorimetric determination of 17 K.S., it is a direct measure of the assayed 17 ketogenic steroids If, as is customary, the figures for 17 K.S. and "total 17 K.S." are expressed in weight units, the resulting values of 17 K.G.S. are about 20% lower than the actual quantities of the estimated 17 ketogenic steroids

Estimation of 17-K.S.

The following procedure is adapted from the method of Drekter et al (1952) 12 glass stoppered centrifuge tubes of about 30 ml capacity are held by spring clips in an H-shaped metal frame From each of six specimens two 8 ml aliquots are placed in the tubes, and 2 ml glacial acetic acid and 3 ml concentrated hydrochloric acid are added to each tube The rack of tubes is kept in a boiling water bath for 10 minutes, then cooled in cold water, to each tube 10 ml ethylene dichloride (purified by shaking with concentrated sulphuric acid and redistilled) is added, the tubes are stoppered and shaken mechanically (in the rack) for 15 minutes The stoppers are now removed, the tubes centrifuged, and the aqueous phases removed with suction The ethylene dichloride extracts are shaken firstly with 2·5 ml distilled water for 2 minutes and then with 2·5 ml 3N sodium hydroxide solution for 5 minutes, after each wash the layers are separated by centrifuging and the upper phases removed by suction The washed extracts are filtered through fluted paper into test-tubes, and from each filtrate two aliquots of 2·5 ml are transferred into smaller test tubes (5 × ½ in.), evaporated on a water-bath kept just below boiling, and finally brought to dryness in vacuo and assayed by the Callow Zimmermann method (Callow et al 1938), as modified by Zygmuntowicz et al (1951), a colour correction (Talbot et al 1942a and b, Medical Research Council 1951) is applied The colorimetric estimation is made on batches of twelve extracts, with each batch two standards of 20 µg dehydroepiandrosterone are included, and the 17-K.S. content of the extracts is calculated from the average standard value The conversion factor from µg per aliquot into mg 17 K.S. per 24 hours is 1·0

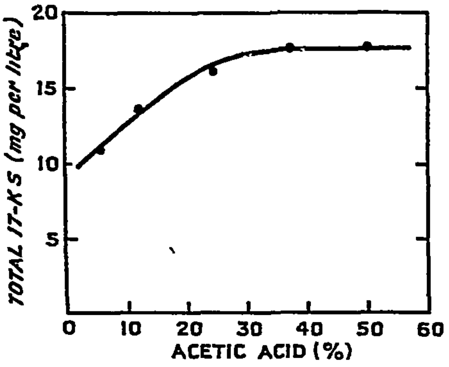

Fig 3—Relation between concentration of acetic acid and assayed "total 17-K S"

TABLE I—COMPARISON OF ORIGINAL AND MODIFIED METHOD

Experimental detail	'Total 17 K.S. (mg per litre)	d_{520} d_{430}
Treatment with NaOH pellets (Original method)	11·2 11·8 8·8 9·3 14·1 12·8	1·0 1·0 1·0 0·9 1·1 1·1
As above with added $NaHSO_3$	16·4 14·7	1·2 1·1
Treatment with aqueous alkali	9·8 8·7 8·4 10·3 9·7	1·5 1·6 1·5 1·7 1·5
As above with added $NaHSO_3$ (Present method)	16·8 16·6 18·0 16·4 16·2	2·2 2·0 2·0 1·8 1·9

Estimation of "Total 17 K.S."

As in the estimation of 17-K.S. two 8 ml aliquots are taken from each specimen and all following operations carried out on a batch of 12 tubes To each tube 8 ml glacial acetic acid and 2 g sodium bismuthate ('Analar') are added The mixtures are shaken mechanically for half an hour with exclusion of direct daylight The stoppers are removed and the tubes centrifuged for 5 minutes at a moderate speed From each supernatant aliquots of 10 ml are transferred into large centrifuge tubes (approximate capacity 50 ml), to each tube five drops of a 5% sodium hydrogen sulphite solution and 10 ml distilled water are added, the mixtures are stirred with a glass rod, treated with 6 ml concentrated hydrochloric acid, and stirred again The hydrolysis and all following operations are performed as in estimating 17 ketosteroids, but using 20 ml ethylene dichloride for extraction and 5 ml water and 5 ml 3N sodium hydroxide solution for washing Of the final extracts two aliquots of 5 ml are taken for the colorimetric estimations The conversion factor into mg "total 17 K.S." per 24 hours is 1·6

VARIATION OF EXPERIMENTAL CONDITIONS

Quantity of Sodium Bismuthate

Apart from corticosteroids other urinary constituents—e.g., sugars—must be expected to react with sodium bismuthate, hence a large excess of the reagent will be necessary for the quantitative oxidation of urinary corticosteroids in situ Fig 1 clearly shows that, for the investigated urine specimen, the quantity of sodium bismuthate used in the standard procedure is in fair excess of that necessary

TABLE II—RECOVERY OF MODEL SUBSTANCES ADDED TO URINE

Type (a)	Substance added (b)	µg of (b) per ml (c)	17 ketosteroid formed (d)	Colour equiv of (d) (e)	Increase of "total 17-K.S." (µg per ml)		% recovery (i)

to the cannula is simply clamped within the pump, the stationary eccentric roller adjusted to act as a tap, and the usual rate of infusion at about 60 drops a minute may be obtained. To increase the rate of delivery the handle driving the roller is turned manually. No other adjustment is required. Flow-rates of about 400 ml. a minute may easily be achieved by using standard transfusion tubing with pump rotation speeds of 60 a minute. This rate has been found to have of itself no undesirable effects in patients (Melrose and Shackman 1951); and, so far as is known, the only other reference to such rates of administration by the intra-arterial route in man is that of Hitchcock et al. (1952). The danger of gas embolism is very remote with this method, and no demonstrable alteration of the blood is brought about during one passage through the pump.

In intra-arterial transfusions it is inadvisable to inject in any quantity anything but blood. Particularly must dextrose solutions be avoided. A small area of skin adjacent to the site of cannulation into the radial artery is often perfused directly during transfusion into this artery. If saline solutions or dextrose is used, the area becomes totally anoxic and may slough; when blood alone is used, this disturbing side-effect is avoided. There is in fact little justification for giving fluids other than blood by the intra-arterial route, since they possess no oxygen-carrying power and the stay of glucose and saline solution within the circulation is evanescent.

At present there is insufficient experience of intra-arterial transfusions to solve all the problems involved. The best rate of administration is not yet known, although it seems probable that the higher rates of about 300 ml. a minute are better. If blood-transfusion is required at lower rates than this, it is generally possible to give it by the intravenous route rather than by the more complicated intra-arterial infusion. The general trend seems to be towards unnecessarily complex machines, even though a simple pump system is adequate.

Fortunately it is becoming appreciated that blood is the only fluid suitable for administration by the intra-arterial route, but we still have insufficient knowledge of the immediate fate of the blood in the circulation, and the advantages and disadvantages of this method of therapy have yet to be assessed.

SUMMARY

Intra-arterial transfusion may be needed to save life.

Blood alone should be used.

If stored blood is used, precautions should be taken that the plasma-potassium level is not dangerously high.

The plasma-potassium level of stored blood increases with length of storage and may exceed 40 mg. per 100 ml. (10 m.eq. per litre)—a concentration which is lethal to man.

Simple decanting of plasma and reconstituting with saline solution or with dextran will lower the plasma-potassium to safer levels.

Rapid transfusions, both intravenous and intra-arterial, are safely and easily given with a simple rotary pump.

We are indebted to Miss M. McKay, Blood Group Reference Laboratory, Chelsea, London, for the samples of pooled plasma.

BOROUGH OF ST. PANCRAS

DURING September, 1949, one of us (D. G.) becam aware of an association between immunisation agai diphtheria and/or whooping-cough and the incidence o paralytic poliomyelitis; accordingly a preliminary repor on the subject was sent to the Chief Medical Officer Ministry of Health, and the Medical Officer of Health fo the County of London.

This association between poliomyelitis and inoculatio appeared to apply chiefly to the use of a diphtheria pertussis combined prophylactic; as a result its use i London was discontinued in the following month.

The matter was submitted to Prof. A. Bradford Hil and Dr. J. Knowelden, who concluded that, in the 194 epidemic of poliomyelitis in this country, cases o paralysis were occurring which were associated with inoculation carried out within the month preceding the recorded date of onset of the illness (Hill and Knowelden 1950). At about the time this matter was made public (Geffen 1950) other reports confirmed these findings, both in this country (Martin 1950) and in Australia (McCloskey 1950).

In 1949 it seemed that this association between inoculation and poliomyelitis was possibly confined to Britain and Australia, for, in correspondence with American authorities, one of us (D. G.) was informed that similar occurrences had not been noted in U.S.A., where both the rate of immunisation and the incidence of poliomyelitis are very high. However, in 1951 Anderson and Skaar, of Minneapolis, published a paper on poliomyelitis occurring after injections of antigen. Their report was based on data collected in 1946. They came to the following conclusions:

> (1) In poliomyelitis patients who had received some antigen in the previous month there was a high degree of correlation between the site of paralysis and the site of injection.
>
> (2) Such cases tended to show a different distribution of paralysis, with more severe involvement, than did comparable children immunised from two to six months previously, in previous years, or not at all.

Fig 2 shows the relation between the reaction time and the assayed "total 17 K S" 30 minutes appears to be a suitable reaction time for the standard procedure

Concentration of Acetic Acid

While pure 17 ketogenic steroids are quantitatively convertible to 17 ketosteroids on oxidation with sodium bismuthate in 1–5% acetic acid (Brooks and Norymberski 1952), it appears that the oxidation in situ of urinary corticosteroids requires a much higher concentration of acetic acid (see fig 3) Furthermore, we find that in the presence of 10% acetic acid only 60% of added dehydroepiandrosterone is recovered from urine submitted to treatment with sodium bismuthate, whereas in the presence of 50% acetic acid the recovery exceeds 90% These observations may be explained if it is assumed that steroids are adsorbed on the surface of sodium bismuthate At low concentrations of acetic acid, and in the presence of large quantities of the reagent, necessary for the oxidation in situ but not for the oxidation of pure substances, the quantity adsorbed can be expected to increase

Other Changes of Experimental Conditions

The estimation procedure in initial experiments (Norymberski 1952) differed in two respects from that now reported (1) the ethylene dichloride extracts were treated with sodium hydroxide pellets as recommended by Drekter et al (1952), (2) no sodium hydrogen sulphite was added after oxidation and before hydrolysis For a time the original method was considered satisfactory, judging by the agreement between separate estimations and by the ratios of optical densities (d) at wave lengths 520 mμ and 430 mμ (Talbot et al 1942a) Occasionally, however, a series of estimations was found to give results which, by both criteria, were unsatisfactory Furthermore, when it became possible to calculate more accurately the recoveries of pure 17 ketogenic steroids added to urine, the recovery figures were found to be rather low The source of the erratic results was finally traced to the treatment with sodium hydroxide pellets and to the presence of an oxidising agent in the supernatant of the urine/acetic acid/bismuthate mixture By substituting for the pellet treatment a conventional aqueous alkali wash, and by reducing the soluble oxidant with sodium hydrogen sulphite, the following improvements were achieved (1) more consistent results of separate estimations (2) increased ratios of d_{520}/d_{430} and (3) higher values for estimated "total 17 K S" Table I illustrates these improvements in a series of experiments which by the original method gave particularly bad results Similar, though less striking, improvements were observed in other experiments designed to compare the original with the present method The greater efficacy of the latter is further demonstrated by the improved recoveries of corticosteroids added to urine

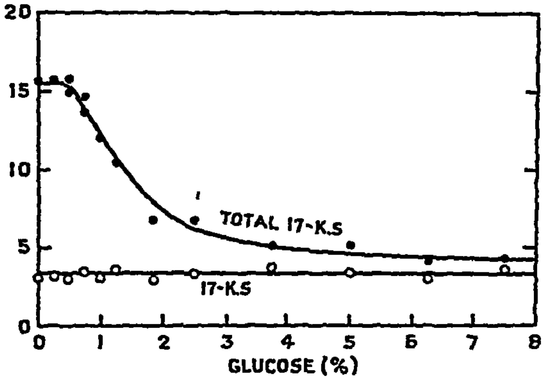

Fig 4—Inhibition by glucose of oxidation of urinary 17 ketogenic steroids

RECOVERY OF 17 KETOGENIC STEROIDS ADDED TO URINE

Norymberski (1952) recorded the recoveries of corticosteroids representing types III, IV, and V Since then the technique of the estimation has been improved and Zimmermann colour equivalents have been determined for 17 ketosteroids derived from model substances used in the recovery experiments We have therefore repeated the recovery experiments (table II)

Wilson (1950) has previously shown that individual 17 ketosteroids can differ considerably in the colour intensities developed with the Zimmermann reagent It was necessary to repeat this work because (1) our colorimetric technique differs from that employed by Wilson, and (2) the colour equivalents of several substances relevant to our work were not recorded Apart from the colour equivalents listed in table II, column (c), those of various other ketosteroids have been determined and will be reported elsewhere

INHIBITION BY GLUCOSE

The experimental conditions laid down in the preceding paragraphs have been found satisfactory in over 200 urinary assays, many of which were checked by the recovery of added pure 17 ketogenic steroids or by varying the quantity of sodium bismuthate Occasionally, however, it may be necessary to assay a specimen with an abnormally high glucose content which could vitiate the determination To test the extent of such interference estimations of 17 K S and "total 17 K S" were carried out on a specimen to which glucose had been added in quantities varying from 0 25 to 7 5% The results, recorded in fig 4, show that with more than 0 5% glucose the estimated "total 17 K S" are significantly decreased It is therefore important to test for

* On phenylbutazone treatment

(3) The interval between injection and the subsequent onset of poliomyelitis suggested some relationship other than chance.

More recently Korns et al. (1952) have studied the association between poliomyelitis and parenteral injections of all kinds by collecting data from 2137 poliomyelitis patients in 1950, from 6055 members of the patients' households, and from 14,710 other controls living in adjacent houses.

They found that their poliomyelitis cases had had twice as many injections of all kinds in the two months before the onset of poliomyelitis than had the controls of similar age, and they conclude that their data tend to indicate that the risk of poliomyelitis is doubled during the two months following an injection of an immunising substance, penicillin, or other materials. In addition, like the workers previously mentioned, they found a positive correlation between the site of paralysis and the site of injection. They state that, although the cases are few, it may be worth recording that in their study the mean interval between immunising injections in the arm and paralysis was twenty-three days, whereas for injections in the leg it was thirty days. They noted that paralysis tended to be slightly more severe after injections than where there had been no injections.

The main aim of our survey reported here was to assess the amount of subsequent recovery in the children who were the subject of a previous report (Geffen 1950).

McCloskey (1952) has also compared the recovery of 25 children whose poliomyelitis had followed recent inoculation (upon whom he had reported in 1950) and 65 children in whom there was no such history. The inoculated groups contained a higher proportion of cases of severe paralysis; but, when cases of equal initial severity were compared, the residual paralysis after eighteen months was not significantly different in the two groups.

Observations

In the earlier report (Geffen 1950) reference was made to 37 children, of whom 30 had developed poliomyelitis within a month of immunisation, the site of paralysis being the site of injection. None of these subsequently died, and we have seen and examined 27 of these 30 children some two years later. Of the other 3, we have full hospital records of the illness and present condition of 2 (cases 2 and 12), but 1 (case 9) remains untraced, though there is no reason to doubt that he is alive.

In order to get a comparison of the extent of recovery, we also obtained the history and examined another 23 children who had not had any recent injection but who had developed poliomyelitis at about the same time in London in 1949, who were of approximately the same age, and in 21 of whom an upper limb was one of the limbs affected.

In the course of examining these children we came across one child (case 28) who had developed paralytic poliomyelitis affecting the left upper arm, the onset of illness being fourteen days after an injection of pertussis vaccine. We have therefore transferred this child to the survey of recovery of children who suffered from post-inoculation paralytic poliomyelitis. We also had referred to us another child (case 29) who received an injection of alum-precipitated toxoid (A.P.T.) on Oct. 5, 1949, in the left arm and developed paralytic poliomyelitis affecting the left upper arm on Oct. 15, 1949, and we have included this child as well.

We have omitted 2 of the original cases for the following reasons:

(1) In one case the interval between injection and paralysis was about a month; but, though the child was injected in

the presence of glucose (e g, with Benedict s solution) before carrying out the estimation of 17-K G S The problem of assaying specimens with a high glucose content may be approached either by increasing the amount of sodium bismuthate or by attempting to remove the glucose prior to estimation

Results of Assays

Some of the results given here can be confidently accepted for interpretation, while others require additional data to make statistically sound generalisations possible Whenever several specimens of one subject were assayed, estimations of creatinine were carried out as well The latter are recorded only for the one case in which they were found erratic

Normal Adults and Children

From the figures in table III no relation is apparent between the excretion of 17-K G S and the age of the adults There seems to exist however a difference between the 17-K G S levels of men and women, the latter being, on the average, about 30% lower

Rheumatoid Disease and Ankylosing Spondylitis

Patients with rheumatoid arthritis or ankylosing spondylitis show considerably lower 17-K G S levels (average about 40%) than normal adults (table IV) Whether this finding is characteristic of these diseases or is simply due to the inactivity that they impose remains to be shown Within this group, as among normal adults, the same relation is discernible between excreted 17-K G S and the sex of the subjects Treatment with moderate doses of salicylate or phenylbutazone does not appear to affect the output of 17-K G.S

Other Conditions

In three cases of pregnancy the 17-K G S figures were found to fall within the normal range (table V) This is of some interest since (1) amelioration of rheumatoid arthritis during pregnancy (Hench 1938) could tempt one to postulate an increased adrenal output of 17α hydroxycorticosterone (Kendall's Compound F) in this condition, and (2) Venning (1946) reported an increased excretion of corticoids (assayed by the liver glycogen test) in pregnancy Urines from patients after operation show, as expected, greatly increased 17-K G S values

Treatment with Cortisone Acetate

The excretion of 17-K S and 17-K G S in a normal male aged 42 was estimated at short intervals for 24 hours before and after a single oral dose of 100 mg cortisone acetate The excretion-rate is graphically recorded in fig 5 The output of 17-K G S returns to normal after 16 hours, about 50% of the total increase is excreted within the first 4 hours, and about 75% within 8 hours This rate of excretion roughly corresponds to the commonly observed period of clinical effectiveness of a single large oral dose

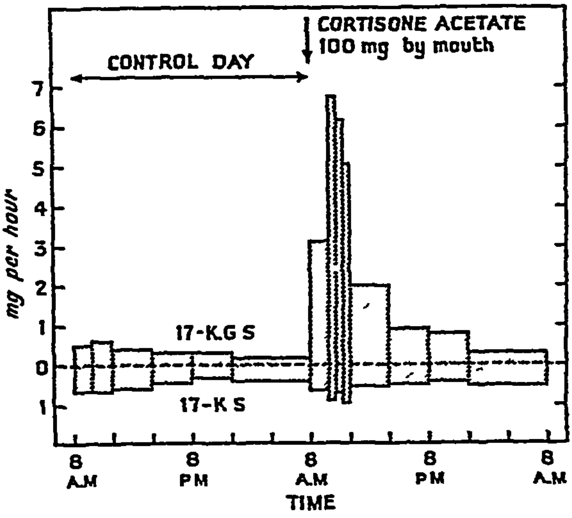

Fig 5—Excretion-rate of 17-K.G.S and 17 K.S after administration of cortisone acetate by mouth

Results of assays on patients receiving between 12 5 mg and 100 mg cortisone acetate daily clearly show proportionality between dose and 17-K G S levels (table VI) The graphic representation (fig 6) exhibits, for doses over 37 5 mg, a straight line passing through the origin We tentatively conclude that oral doses of about or above 37 5 mg cortisone acetate can almost completely suppress the endogenous production of 17-ketogenic steroids It is interesting to note that this figure corresponds with the minimum dose that produces benefit in rheumatoid arthritis

the left arm, it was the right shoulder and left leg which were mainly affected.

(2) In another case the interval was about a month, but there was no definite information about the site of the inoculation.

Originally some doubt was expressed as to whether the paralysis ensuing on inoculation in these and similar children was in fact due to poliomyelitis. As it is now generally accepted that this is so, we shall not discuss the matter in detail; but it is of interest that MacCallum (1950) isolated poliomyelitis virus from the stools of 2 of our children who had been inoculated in the subsequently paralysed limb eleven and twelve days previously. Further, 26 of our 29 inoculated children had a lumbar puncture in the acute stage of their illness, and the cerebrospinal fluid was characteristic of poliomyelitis.

Table I relates to 29 children who developed poliomyelitis in 1949 following recent inoculation, the limb of inoculation becoming subsequently the limb of major paralysis or one of the parts maximally involved. The extent of paralysis at the height of the illness and about *two years later (" present state ") was assessed in accordance* with the following scale, which is similar to that adopted by McCloskey (1952):

Very Severe.—Flaccid paralysis involving the major part of an extremity.

Severe.—Paralysis of at least one muscle group.

Moderate.—Partial paralysis of at least one muscle group.

Slight.—Slight paralysis involving a muscle group.

Nil.—No detectable weakness.

TABLE III—AGE AND SEX DISTRIBUTION OF THE INOCULATED AND CONTROL GROUPS

Age at onset (mths)	Inoculated			Controls		
	Males	Females	Total	Males	Females	Total
Less than 12 ..	6	7	13	2	2	4
12–23	8	4	12	5	4	9
24–35	1	1	2	4	2	6
36 or more ..	1	1	2	2	2	4
Total ..	16	13	29	13	10	23

CONTROLS

For purposes of comparison we obtained details of 23 children who had acute poliomyelitis in the same epidemic and in the same city (London) as did our inoculated cases. We have also examined them recently—*i.e., from two to two and a half years later.* Their particulars are set out in table II. These children were about the same age as the inoculated children, and in 21 of them an upper limb was one of the limbs affected.

Unfortunately we were not able to match the two groups accurately in respect of these factors, but in respect of age all but 27 of the 29 inoculated children and 19 of the 23 controls were aged less than 3 years when they contracted poliomyelitis. The sex-distribution was about the same. Table III summarises the age and sex distribution in the two groups.

INTERVAL BETWEEN INOCULATION AND ONSET OF POLIOMYELITIS

Table I shows that the interval between the last injection and the onset of poliomyelitis was from five to thirty-six days. Here a difficulty arises because in some cases the first day of the disease is reported as the day the first symptoms were noticed—often diarrhœa and vomiting, restlessness, or the like—whereas in other cases the first day of illness obviously refers to the time when *paralysis became evident.*

We have carefully examined the cases where the incubation periods are twenty-one or more days, and we find the position to be as follows:

Case 3.—Here the interval was twenty-one days between immunisation and onset of poliomyelitis, and there was flaccid paralysis of the left upper arm by the time the child had been admitted to hospital. The onset was said to have been sudden, but there is a history that the child had diarrhœa, passing five or six greenish stools, three or four days previously.

Case 10.—Here the interval was twenty-six days, and the child had been treated at home with *sulphonamides* for tonsillitis two weeks before the mother noticed that he could not sit up or use his arms.

Case 13.—Here the interval was twenty-two days between injection and the day on which stiffness of the neck and spine, with commencing paralysis, came on.

Case 16.—Here the interval was twenty-four days. There were two notes: a statement, made by the mother two years later, that the child had had an injection a week before he *was taken to hospital; and a note in the hospital records* to the effect that the child had been immunised two weeks before admission. The official date, however, given us for the last injection by the medical officer of health of the district in which the child was resident, was Aug. 16, 1949, twenty-four days before the onset of poliomyelitis.

Case 26.—Here the interval was thirty-six days, and poliomyelitis was *not diagnosed* before the boy was taken to hospital by his mother because he was not using *his left arm.* On admission there was complete flaccid paralysis of this limb. There is no history of illness before this, but possibly there were preparalytic symptoms which escaped recognition.

It is not surprising that in many cases the diagnosis rests on the presence of gross paralysis, because the patients were mostly of an age at which minor illness would not be associated in the mother's mind with the onset of poliomyelitis. Further, it *is of course* quite that it is thyroid deprivation, and not a toxic effect of the drug, which harms the fœtus They concluded that if the mother's metabolic rate is kept within normal limits the fœtus should be unharmed, but that if the mother becomes myxœdematous, the fœtus will share the same fate In pregnancy the metabolic rate remains at the normal level until the sixth month, and may then rise as high as +25% Therefore, when a woman in late pregnancy is receiving thiouracil, her metabolic rate should not be allowed to fall to normal, for the mild hypothyroidism induced may result in a deficient supply of thyroid hormone to the fœtus On the basis of experimental work, the human fœtus and suckling infant might be expected to suffer if thiouracil and related drugs are administered during pregnancy Several reports have been published on the offspring of mothers who received thiouracil or a derivative for the whole or part of pregnancy

PREVIOUS REPORTS

Williams (1946) treated 5 women, including 1 with a twin pregnancy The 6 infants were healthy at birth and none had a goitre Astwood and Vander Laan (1946) treated 3, Reveno (1948) 3, Sexton (1946) 2, Trotter (1951) at least 4, and Rose and McConnell (1944), Vogt (1946), Carns and Poser (1946), Caren (1949), Bain (1947), and Eisenberg (1950) each treated 1 case, and all these babies were normal Palmer (1945) treated 3 women, and the only infant on which she reported fully was normal

Whitelaw (1947) described 3 cases only 2 carried to term, and 1 baby was normal, the other was an anencephalic monster The weight, iodine content, and histological appearance of its thyroid gland were within normal limits

Lahey and Bartels (1947) treated 8 pregnant women, and Mussey et al (1948) 1, by partial thyroidectomy following preparation with an antithyroid drug Each patient delivered a normal infant at term Bell (1950) treated 21 pregnant women in the same way 10 of his patients were delivered at term of 11 normal infants, who developed normally while under observation for periods ranging from eleven months to five years, 6 women had not reached term when the report was written, and 1 woman aborted There were 2 premature deliveries, 1 of the babies being macerated, while the other was deformed and died in four hours Another baby died at birth, and another, delivered by cæsarean section, died at six hours The condition of the thyroid glands of these infants was not reported

10 cases have been reported in which abnormality in the fœtus or infant was considered to be due to the passage of thiouracil through the placenta

Davis and Forbes (1945) described the case of a woman who was taking 0 2 g of thiouracil daily when she became pregnant After the diagnosis of pregnancy in the second month she took 0 2 g on alternate days until the sixth month when she died suddenly, her death being unexplained The fœtus had a hyperplastic and hypertrophied thyroid gland the histological appearance being similar to that found by Donald and Dunlop (1945) in an adult receiving too much thiouracil Davis and Forbes ascribed the effect to the direct action of thiouracil on the fœtal thyroid gland, rather than to lack of maternal thyroxine for the mother was not myxœdematous Freiesleben and Kjerulf-Jensen (1947) treated a pregnant patient with methylthiouracil until the fifth month, when the fœtus was removed because the pregnancy was complicated by heart failure The fœtal thyroid gland was hyperplastic Eaton (1945) reported 2 cases in which thiouracil was given during pregnancy The first patient began with thiourea in the third month and this was later replaced by thiouracil which was continued until four weeks before term The baby was healthy The second patient was receiving thiouracil (600 mg daily) when she became pregnant, and took this dose throughout the first month and from the third to the fifth months The dose was reduced to 400 mg daily for another month and then to 200 mg daily until delivery which was by cæsarean section because of placenta prævia Three months before delivery the mother's basal metabolic rate was + 5% The baby had an enlarged thyroid gland but was otherwise normal The enlargement had subsided after three months, and growth had been normal

Frisk and Josefsson (1947) described the case of a woman who was taking methylthiouracil (100–200 mg daily) when she became pregnant The dose was increased to 200 mg daily after three months Treatment was stopped for six and a half weeks but 300 mg was given daily for the last seven weeks The patient never had signs of myxœdema and the basal metabolic rate was usually +10% with a minimum of +5% Uterine myomata necessitated delivery by cæsarean section two weeks before term The baby was in fairly good general condition, and the thyroid gland was not clinically or radiologically enlarged, but X ray examination of bones showed retarded development of centres of ossification, the appearance being that of an eight month fœtus The serum cholesterol was 145 mg per 100 ml The baby was not breast fed, and during the first month there was no obvious abnormality in the general condition or behaviour, apart from moderate hypochromic anæmia In the second month she became agitated and developed exophthalmos Spontaneous improvement began after two months, and in three months the child seemed normal for her age, apart from the exophthalmos which subsided by the eighth month The authors explanation is that thiouracil blocked fœtal synthesis of thyroxine resulting in increased activity of the hypophysis Maternal thyroxine prevented myxœdema in the fœtus and suppressed thyrotropic activity, but when the drug was withdrawn, pituitary hyperfunction persisted

Keynes (1952) described a baby, whose mother received methylthiouracil and sodium thyroxine throughout pregnancy, who, at delivery, had partly obstructed breathing due to a large thyroid swelling which regressed over the next nine days X ray examination showed delayed ossification He also recorded the condition at birth of 19 infants whose mothers had received thiouracil compound during pregnancy 12 mothers had received the drug for a short time only, and the babies were normal 6 had received it for a longer period Premature twins were born to 1 mother 2 other babies were cretinous with swollen necks, 1 was cretinous without goitre, and 2 had goitres 1 of the cretinous babies with a goitre was the case described below, and Keynes gives the baby's history in the mother's own words

No case has been reported of a mother taking thiouracil who breast fed her baby

The following case is described because a search of the literature has revealed no other report of an infant, whose mother was treated with thiouracil during pregnancy, who besides having a large thyroid gland, showed clinical signs of hypothyroidism at birth and failed to develop normally

CASE RECORD

Mrs A, aged 29, was first seen in the antenatal clinic on May 2, 1950, when she was four and a half months pregnant She had 2 normal children, aged 5 and 2 She had severe thyrotoxicosis, the symptoms having begun thirteen months previously Treatment with methyl thiouracil (200 mg twice daily) was begun on May 25 and was continued throughout pregnancy and the puerperium At term there was no evidence of thyrotoxicosis apart from exophthalmos Hydramnios developed, and artificial rupture of the membranes was performed at term on Oct 5 1950 fourteen pints of liquor being withdrawn The baby was delivered spontaneously on Oct 8 after a labour complicated by uterine inertia Her colour was good, and she cried at once Her weight was

The baby on the fourteenth day

possible for a parent to miss paresis or paralysis when a baby is ill, listless, and apathetic, and has to have everything done for it. The preparalytic symptoms observed in our cases are discussed below.

Fig. 1 is based on the intervals stated in table I, and shows that the average interval was about thirteen and a half days, being twelve days in 5 cases, from five to eleven days in 13 cases, and from fourteen to thirty-six days in 11 cases. In 24 cases (more than 82%) it was from five to sixteen days. We doubt whether some of the longer intervals are correct. The point is important because in a district where poliomyelitis is present, the medical officer of health and the physicians practising there are anxious to know the maximum duration of the period of risk in this connection. It is also important in differential diagnosis. Hill and Knowelden (1950) say:

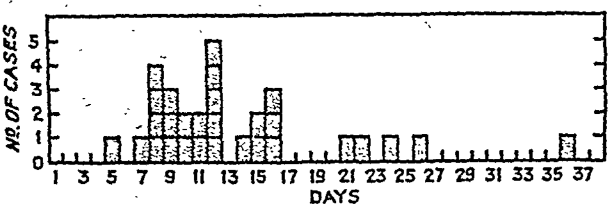

Fig. 1—Number of days between injection and onset of symptoms of poliomyelitis.

> "There is no evidence whatever that inoculations carried out in the more distant past have any effect at all upon the incidence or localization of paralysis. These effects appear to be confined to injections given within about a month of the onset of poliomyelitis, and after that interval from inoculation has elapsed no risk need be envisaged."

While agreeing entirely with this statement we think that the period of risk can be further shortened. Taking into consideration the possibility that some mothers have not sought medical advice until such time as illness is acute or paralysis is present, it is probably fair to say that, if a child shows no signs of illness distinguishable by a medical practitioner within two or three weeks of injection, the period of risk has passed.

PREPARALYTIC DISTURBANCES

In table IV the preparalytic symptoms and signs recorded in the inoculated and control groups of children are summarised. These are in almost every instance such that it would be difficult for a layman to associate them with poliomyelitis. In both the inoculated and control groups the commonest manifestations are fever, vomiting, drowsiness, and injected fauces. Most of our children were too young to complain of headache; those that did were aged 2 years or more.

TABLE IV—PREPARALYTIC SYMPTOMS AND SIGNS IN 29 CHILDREN WHO DEVELOPED POLIOMYELITIS AFTER INOCULATION AND IN 23 CONTROLS

Symptom or sign	Inoculated group	Controls
Fever	20 (*69%*)	16 (*70%*)
Vomiting	17 (*58%*)	9 (*39%*)
Drowsiness	16 (*56%*)	9 (*39%*)
Injected fauces ..	13 (*45%*)	5 (*22%*)
Anorexia	8 (*28%*)	3 (*13%*)
Diarrhœa	6 (*21%*)	2 (*9%*)
Headache	3 (*11%*)	2 (*9%*)
Coryza	0 (*0%*)	4 (*18%*)

Clearly the numbers are too small to allow any conclusions to be reached about any significant differences in the preparalytic symptoms in the two groups. In any case it has already been seen that the inoculated children were somewhat younger than the controls, a factor which might well influence their preparalytic signs and symptoms.

TABLE V—PARALYSIS IN INOCULATED LIMBS OF 29 CHILDREN

Slight ..	..	..	..	..	..

One child was inoculated in both thighs.

EXTENT OF RECOVERY

Tables I and II reveal the degree of recovery in approximately two years in the inoculated limbs in our 29 patients with post-inoculation poliomyelitis and in the most severely affected limbs in the 23 controls.

Tables V and VI summarise this information for purposes of comparison between the two groups. They show, as one might expect, that the degree of recovery in either group is related to the severity of the original paralysis. In addition, however, they show that, whereas the paralysis in the inoculated limb was nearly always initially severe or very severe, the limb of major paralysis in the controls was not uniformly seriously affected.

The state of all four extremities in both groups is summarised in tables VII and VIII, where the degree of initial involvement is contrasted with the residual state found some two years later. It will be seen that in the series of 29 inoculated children 46 out of 116 limbs (39·7%) were involved; the comparable figures for the controls being 49 out of 92 (53·3%). This difference tends to confirm our clinical impression that the paralysis of post-inoculation poliomyelitis, though severe, was more limited in extent than in comparable uncomplicated cases. The initial paralysis was severe or very severe in 39 limbs of the injected children, and in 27 cases (69·2%) remained so two years later. A similar state was found in the controls, the comparable figure being 64%. It therefore seems that the difference in recovery in limbs affected to a more or less equal extent in the inoculated and control groups is not of significance.

Discussion

PROPHYLACTIC AGENT

Table I shows that a combined diphtheria-pertussis prophylactic was used in 19, A.P.T. in 8, and pertussis vaccine alone in 2 of our 29 children who subsequently developed paralytic poliomyelitis. Unfortunately we do not know the over-all proportion of children immunised

6 lb 7 oz She was œdematous all over but no more so than some healthy infants The anterior and posterior fontanelles were widely open The eyes appeared widely spaced and the bridge of the nose was depressed (see figure) The thyroid gland was diffusely enlarged Breast-feeding was not allowed.

During the next twenty-four hours other abnormalities became apparent The baby was very lethargic, she cried and moved infrequently, and her muscle tone was poor There was persistent cyanosis of the extremities and the skin felt cool Attempts at sucking were feeble and feeds were taken very slowly For the first few days the rectal temperature never rose above 97 2°F, and the pulse rate varied between 100 and 110 per minute Apart from further enlargement of the thyroid gland her condition remained stationary for several days after which she improved in every way

On the fifteenth day when she was discharged, she was still lethargic and hypotonic but sucked strongly, and crying was infrequent but lusty The skin felt warmer and there was only occasional peripheral cyanosis The thyroid swelling was subsiding Rectal temperature was 98°–98 4°F and the pulse rate 110–120 The serum cholesterol level was 130 mg per 100 ml on the thirteenth day Although this level was within normal limits, it is not considered to invalidate the diagnosis of hypothyroidism. for there was considerable clinical improvement by the thirteenth day, and in young untreated cretins the serum cholesterol level may be within normal limits (Bruch and McCune 1944, Topper 1951, Wilkins and Fleischmann 1941)

Owing to domestic difficulties, Mrs A failed to keep appointments, and the baby was not seen again until June, 1951 when she was eight months old She had followed a light with her eyes at two months, and had smiled at four months She had always been lethargic, and had only recently begun to kick her legs or hold up her head She was plump and hypotonic, and still had the strange naso-orbital configuration She smiled and took notice of what was going on but did not reach out to grasp objects, kicked feebly, and could only lift up her head momentarily The pulse rate was 110 and the skin was warm and pink. No thyroid enlargement was detected No other abnormalities were found and there was no evidence of hypothyroidism.

Two weeks later a lower central incisor erupted, and at nine months she could kick vigorously, hold up her head and sit up with slight support, though she could not pull herself up X-ray examination of the carpus showed centres of ossification for the os magnum and unciform bones on both sides, and diaphyseal dysgenesis was not present

From Sept 5 until Oct 3, 1951, thyroid was given (the dose is unknown), but it was stopped because it was considered to be unnecessary The mother noticed no change during this period.

Her subsequent progress has been disappointing The mother reported at seventeen months that the baby was lively and contented, but backward. She could pull herself up into a sitting position but could not sit or stand without support, and had made no attempt to crawl She had spoken no intelligible words, and played with toys like a much younger child She was neither clean nor dry The anterior fontanelle had almost closed She had twelve teeth Her weight was 22 lb, and her height 33 in

DISCUSSION

Thyroid enlargement in the infant of a mother who received methylthiouracil during pregnancy, and its disappearance after withdrawal of the drug at birth is to be expected in the light of experimental work (Hughes 1944 Goldsmith et al 1945 Freiesleben and Kjerulf-Jensen 1946) although few cases have been reported

The hypothyroidism exhibited by this baby is not difficult to explain On the thirteenth postpartum day her mother's basal metabolic rate was —5%, and the serum-cholesterol level was raised to 375 mg. per 100 ml As treatment had been unchanged, she had probably been mildly myxœdematous during the latter part of pregnancy The fœtus whose own thyroid function was depressed by thiouracil must therefore have been receiving insufficient thyroid hormone After withdrawal of the drug at birth the infant's thyroid gland recovered quickly and produced enough thyroid hormone to cure the hypothyroidism and prevent its recurrence

At nine months mental development was retarded, although physical and skeletal development were satisfactory, and there was no evidence of hypothyroidism Mental retardation may occur in congenitally hypothyroid children in spite of apparently adequate therapy (Aldrich 1936, Bruch and McCune 1944, Lewis 1937, Wilkins and Fleischmann 1941), and Topper (1951) and Bruch and McCune (1944) consider that cerebral damage is the factor which prevents satisfactory mental progress Lotmar (1929) found histological changes in the brain cells of cretins after death which he thought to be due to the effect of thyroid deficiency. Tredgold (1929) believed that there were two types of cretin · in one type mental and physical retardation were due to hypothyroidism. and the child became normal under treatment, in the other, the essential condition was primary amentia, the hypothyroidism being a complication, and the child remained mentally defective in spite of treatment

In the case reported here, it is not possible to tell whether prenatal lack of thyroid is the sole cause of backwardness, or whether primary amentia exists as well The strange facial appearance, which is unlike that of a cretin or of any named condition, makes the child appear defective It is not likely that better progress would have been made if thyroid had been given, for recovery from the early hypothyroidism took place spontaneously There is evidence that thyroid hormone may impair mental capacity when given to cretins in amounts greater than those required for satisfactory physical growth (Bruch and McCune 1944), although Aldrich (1936) advocated giving the largest dose of thyroid tolerated by the patient, in case more thyroid were needed to produce normal mental development than to provide satisfactory physical growth

This case is reported in order to draw attention to the fact that the administration of thiouracil to a pregnant woman may give rise not only to thyroid hyperplasia, but also to hypothyroidism and permanent damage in the fœtus The danger could be minimised by careful control of the dosage, so that the mother is not allowed to become myxœdematous In view of Keynes's report that the babies of mothers who had received the drug for a short time only were healthy, and that 5 out of 7 whose mothers had received it for a longer time were abnormal, it is clearly advisable to give it only for short periods

SUMMARY

Experimental work on animals has shown that the administration of thiourea or its derivatives to pregnant animals may lead to thyroid hyperplasia and cretinism in the young animal

Only 10 cases of abnormality ascribed to thiouracil in the human fœtus or newborn infant have been reported These are described

A baby girl, whose mother received thiouracil during pregnancy, had hypothyroidism at birth She recovered spontaneously, but her mental development was subsequently retarded

The cause of the hypothyroidism and mental retardation is discussed

I wish to thank Dr Simon Yudkin for his help and encouragement in the preparation of this paper.

with a combined reagent, compared with A.P.T. and pertussis vaccine in the areas whence these children came in 1949. Such a small series would render invalid any attempt at assessing the relative danger incurred in using any particular type of prophylactic in these circumstances. Yet it is generally agreed that the combined prophylactic was implicated in that year more often than would have been explained by the frequency with which it was used. Perhaps it is significant that, since the use of this vaccine in London clinics was discontinued in October, 1949, very few cases of post-inoculation poliomyelitis have occurred in the London area, although due allowance must be made for the fact that in the subsequent two years far fewer cases of poliomyelitis were notified in the age-groups concerned.

To reduce the local reaction following the inoculation Bousfield (1950) advises subcutaneous instead of intramuscular injection of the reagent. We do not know whether this would have a significant effect on the issue, for we have no information about the depth of the inoculations given in our series or in other children of the same age so protected at that time.

AGE OF INOCULATED CHILD

Bousfield (1950) has also suggested that immunisation during the first few months of life would minimise the risk of post-inoculation poliomyelitis. This may be true to some extent, but it is clear that poliomyelitis may give rise to paralysis in even the youngest infants. Smallpeice and Ounsted (1952) described 3 such cases in infants aged 7, 3, and 2 weeks. Wright and Owen (1952) recorded 3 similar examples of early infantile poliomyelitis. Logan (1952) published figures showing the incidence of poliomyelitis in England and Wales in 1950 for children aged less than 1 year: 254 such children were notified as having paralytic poliomyelitis. Of these, 10% were aged less than 3 months and 18% between 3 and 6 months; hence 72 (28%) of these children had paralytic poliomyelitis before they were 6 months old. It therefore seems unlikely that earlier immunisation would effectively prevent this serious complication.

POST-INOCULATION POLIOMYELITIS AND ANTI-DIPHTHERIA CAMPAIGN

The association between injections and poliomyelitis has naturally received some publicity in the lay press as well as in medical journals, and many medical writers have suggested that this has been unfortunate in that it has given rise to public alarm which has been both unnecessary and out of proportion to the actual situation. It has been argued, for example, that the recent reduction in the number of children immunised against diphtheria is due to this cause, although Gray and Cartwright (1952) have recently concluded that the fear of contracting poliomyelitis after immunisation does not at present constitute a factor of importance in the immunisation campaign. So far as our experience is concerned, we are in agreement with them, having questioned mothers whose children contracted poliomyelitis in 1949 in these circumstances, and who have since had another child.

If the incidence in London of diphtheria and poliomyelitis in recent years (*fig. 2*) is *considered*, it is easily seen that the public in this city has every reason to be more worried about poliomyelitis than diphtheria, no only because the case-incidence and death-rate of polio myelitis are higher but also because the crippled stat of some of the survivors of acute poliomyelitis contrast forcibly with the present rarity of serious diphtheriti sequelæ.

We believe that the public is entitled to know th facts of the situation. These should be put before then fairly and without exaggeration, for in our experience a well-informed public can assess the situation and mak a wise decision.

Summary

A report is presented showing the extent of recovery of 29 London children who developed paralytic poliomyeliti in 1949 after a recent inoculation. Comparison is made with 23 children of about the same age who had not had a recent inoculation but had developed paralytic poliomyelitis during the same epidemic, and in 21 of whom *an upper limb* was affected.

There was no fatality in the 29 inoculated children.

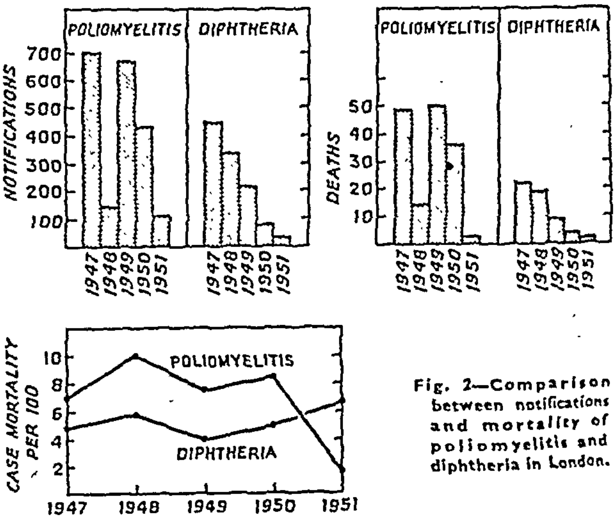

Fig. 2—Comparison between notifications and mortality of poliomyelitis and diphtheria in London.

The average interval between inoculation and the onset of poliomyelitis was thirteen or fourteen days; in over 80% of cases it was between five and sixteen days. It is probable that three weeks after inoculation the *period of risk* has passed.

The preparalytic symptoms recorded in the 29 inoculated children were in the main similar to those observed in the controls.

The paralysis of poliomyelitis following recent inoculation appears to be relatively limited in extent. When paralysis occurs in an inoculated limb, such paralysis is nearly always severe. Recovery of a limb appears *to depend on the initial severity of the paralysis, irrespective* of whether the limb has been inoculated or not. The extent of recovery which took place in two and a half years *in both the inoculated and control groups* was *related to the severity* of the *original* paralysis.

In the 29 inoculated children there was *no information* that the inoculations were intramuscular rather than subcutaneous.

It is considered doubtful if immunisation at an earlier age would prove effective in avoiding post-inoculation poliomyelitis.

It has not been proved that lay publicity on post-inoculation poliomyelitis is the reason for recent reduction in the number of *children immunised* against diphtheria. We are of opinion that the public is entitled to have the facts put before them clearly.

This work was done with the support and help of a grant from the Medical Research Council.

References at foot of next column

(1) ladder climbing (figs 2 and 3), (2) holding leads from a fearsome looking X ray switch panel with suggestion of increasing current as switches are pressed and knobs turned, although no current is passed at all (fig 4), (3) locked up in a small dark room, (4) making a public speech, (5) balancing at a height, and (6) fire extinguishing drill (fig 5)

Muscle action potential can also produce a β frequency in the E E G, but this artefact is excluded by voluntary test movements before the exercises.

(1) Failure to produce β by voluntary muscular effort Frowning, looking surprised, head-turning teeth-clenching arm raising, walking, arm-straining leg-raising, leg-straining

(2) Where possible, repetition of the test in absence of anxiety without occurrence of β For example, ladder-climbing may be done repeatedly without production of β and then show β when situations are altered to produce anxiety on climbing

(3) Absence of β during similar active movement when there is absence of β-productive situation—i e, a quiet base line except during the anxiety situation.

β frequency is the term applied to rhythm at 14–25 cycles per sec It is especially seen in the frontal areas and is thought in some cases to be associated with anxiety. For example, it was noticed in one exercise that in four different men β rhythm occurred when they reached the middle of an extension ladder (fig 6) This *appeared* on inspection to be associated with either increased sway in the middle of the ladder or a rope knot at this point requiring careful negotiation No conclusions are intended from this particular illustration, but one may speculate whether the instrument could be used in this way to indicate the points of irritation or special attention in performance of a given task—e.g, routine factory job—and perhaps lead to elimination of points of difficulty in the job performance, or as objective evidence of acquisition of confidence during learning of a particular act Perhaps we have a machine here which will give us objective evidence of anxiety as opposed to subjective

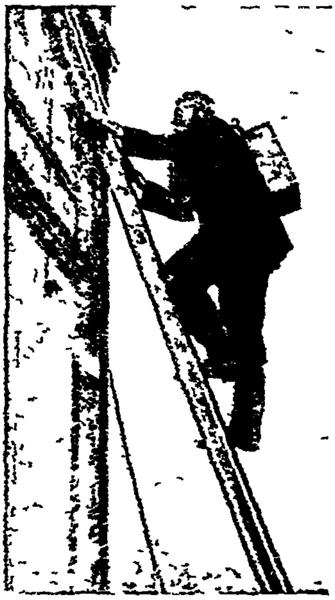

Fig 3—Man climbing ladder while wearing apparatus for recording E.C.G and E.E.G

A further point which has arisen in our initial tests is that the prefrontal cortex is relatively quiescent for considerable periods during continuous recording For example, in one subject there was no great activity throughout a game of deck tennis and "shooting in" at football, whereas in the same subject β activity is easily provoked by anxiety situations of a particular kind It also seems from our initial tests that different people exhibit β in anxiety situations peculiar to themselves—e g, climbing a ladder might never produce β in one person but being shut up [illegible] dark room would [illegible] In one test a fireman got stuc [illegible] underside of a ladder at roof height when the [illegible] ught in the ladder rungs This gave him "a ve [illegible] moments" and was reflected in the E E G as [illegible] burst of high voltage β activity (fig 7) [illegible] ies the spontaneity of the situations which [illegible] ing, be so different from the normal E.E G, taken at rest

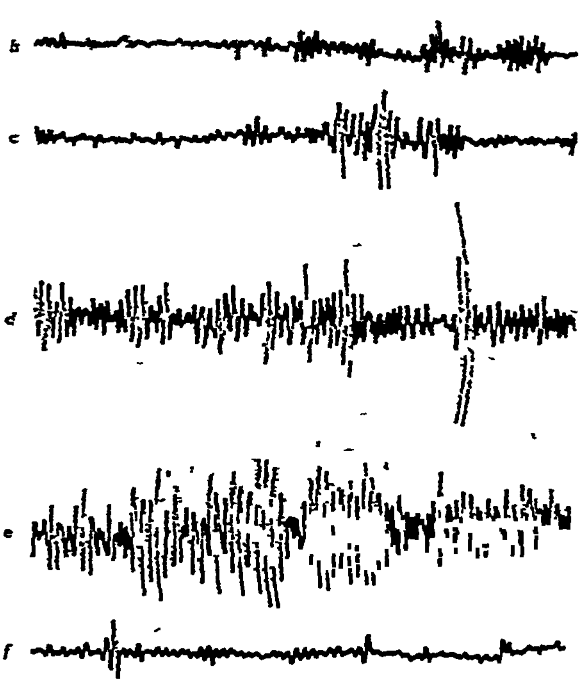

Fig 4—E.E.G of person, holding leads from electric switch panel who has been told that he will feel increased current when switches are pressed and knobs turned, although no current is passed at all a before test b, while test is being explained, c while knobs are being turned, d, when big switch is pressed, e, when 'full power' has supposedly been turned on f, after test. Note increasing β activity while switch panel is being manipulated

One of the probable reasons why the E.E G has been of less immediate clinical application in psychiatry than might have been thought is that recording has hitherto had to be done with the subject at rest This portable apparatus now enables us to study the E E G in everyday situations

Fig 8 compares an ordinary direct E E G recorded simultaneously with a radio E.E G

The Apparatus

The design of a suitable radio transmitter presented many difficulties, the main requirements being economical operation to restrict weight of batteries or other power supply, small size, and an almost infinite capacity to withstand rough usage during the tests (fig 9)

Fig

A METHOD OF TREATMENT FOR VARICOSE VEINS

MICHAEL G. WILSON
M.B. Leeds, F.R.C.S.
SENIOR SURGICAL REGISTRAR, BRISTOL ROYAL INFIRMARY

THE method of treatment described here has been used in 50 cases at the Bristol Royal Infirmary with encouraging results.

There is general agreement that when the internal saphenous vein is incompetent and varicose the first step in treatment is its ligation at the point of entrance into the femoral vein. But usually this does not suffice for cure, and many different procedures have been introduced to deal with the residual varicosities in the leg:

Excision of the vein through a long incision (Madelung 1884) is a major procedure which is very occasionally necessary but leaves an unsightly scar. The vein may be removed through small incisions with Mayo's (1906) stripper or Babcock's (1907) acorn-tipped guide. Both these methods tear across tributaries and may cause hæmatomata.

Sclerosants may be injected to obliterate the vein either after operation (Tavel 1904) or at the same time (Schiassi 1908). A ureteric catheter may be used to make the injection (Unger 1927). Disadvantages of the use of sclerosants are the production of thrombosis in the deep veins (Atlas 1943), damage to valves in the deep veins (Kinmonth 1948), and, if the injection is made at the time of operation, a painful leg which tends to discourage early ambulation.

Electrocoagulation as an alternative or an adjuvant to the use of sclerosants by passing a cystodiathermy electrode along the vein was suggested by Smith (1944), but there is difficulty in passing the electrode along tortuous veins and in regulating the current. All these methods of inducing clotting in the veins may be followed by recanalisation.

Multiple ligature of the internal saphenous vein is now the most popular method of dealing with varicosities, and the tendency is to tie the vein in more places. Sclerosants are being reserved to obliterate what varicosities remain after multiple ligature and for minor varicosities of the calf without demonstrable incompetence of the main saphenous trunk.

McElwee and Maisel (1947), following on the work of Moore and Knapp (1942) at the New York Hospital, have compared the results obtained in five different methods used unselectively, and placed them in the following order: (1) multiple ligation; (2) high ligation and retrograde injection; (3) high ligation and stripping; (4) high ligation and excision; and (5) high ligation alone. In all cases postoperative injections were given to complete the obliteration. Although McElwee and Maisel concluded that multiple ligature (with an average of four ligatures) gave the best results in their follow-up (average of eighteen months), they record that an average of 3·4 injections was required later to complete the obliteration, and that minor wound sepsis and delayed healing were troublesome.

The more ligatures, within reason, that are used at the primary operation, the fewer injections are needed later and the better the end-results should be; but as the operation becomes more lengthy and severe, the patient becomes less willing to be ambulant immediately afterwards. Also the incidence of minor wound troubles is higher, and an operation which may have been performed largely to remove unsightly veins may substitute unsightly scars.

A method which can increase the number of permanent interruptions of the veins and at the same time abolish the incisions down the leg would have obvious advantages over those discussed hitherto. Goldstone (1943) suggested, as a substitute for high ligation, the passage of a ligature round the upper part of the saphenous vein by a neat trick in which only two punctures are made, the ligature remaining in situ under the skin. As a substitute for a formal high ligation this is unacceptable; but, if a non-absorbable ligature material, such as braided 'Nylon' is used, it is an effective means of applying multiple ligatures. It is done quickly—a dozen ligatures can be placed in as many minutes—and leaves practically no trace. Consequently a larger number of points can be reasonably ligated, and all the varicosities can usually be completely obliterated at the primary operation. This is the basis of the method described here.

Other percutaneous methods, notably those of Davat (1837) and Schede (1877), have been described; but they are not comparable, because the ligature was tied outside the skin and removed later.

In Davat's method a needle was passed through the skin under the vein and left there while a figure-of-eight ligature was tied tightly round its protruding ends. In Schede's method the ligatures were tied over a rubber tube. In both methods the object was to induce thrombosis and perhaps to cut through the vein. Neither method was very successful; both are crude and have long been obsolete.

Technique

Preliminary Marking

The marking out of the veins before operation is of great importance because it is then that the situation and numbers of ligatures to be used are decided. Hartley's ink * is suitable for this purpose; it produces a deep black mark which does not wash off when the skin is "sterilised" at operation. The incompetent internal saphenous vein is marked off at intervals of 2–4 in. wherever it can be seen or palpated; varicose tributaries are also marked off and at shorter intervals if necessary. Where a large varix is very close to the skin and appears to be adherent to it, ligatures are placed above and below. It is probably better to avoid tying veins immediately over the subcutaneous border of the tibia, especially if the patient is thin.

A suitable method of marking is to place a dot where the punctures will be made, on either side of the vein and about $^3/_4$ in. away from it, so that the two dots are about $1^1/_2$ in. apart with a dash between to link them (fig. 1). If there are large blow-outs that need excision, a line is placed over them.

In some cases it is helpful to have an infra-red photograph of the leg beforehand. This helps one to understand the pattern of the varicosities and is also a permanent record (fig. 2). The results are somewhat variable and depend on the thickness of the patient's skin and the amount of subcutaneous fat.

Operation

Under general anæsthesia the skin of the whole leg is cleaned; the foot is towelled separately, so that the whole leg can be freely moved and veins on the back of the calf reached without turning the patient over.

For the high ligation a transverse incision is preferred to the vertical one, which, though affording better access

---

* Hartley's ink is one of a number of inks sold for marking garden labels. It produces a thick black mark that is insoluble in water or in spirit. Dr. W. A. Gillespie, who kindly carried out some bacteriological tests, found it sterile on culture on aerobic and anaerobic blood-agar and in broth.

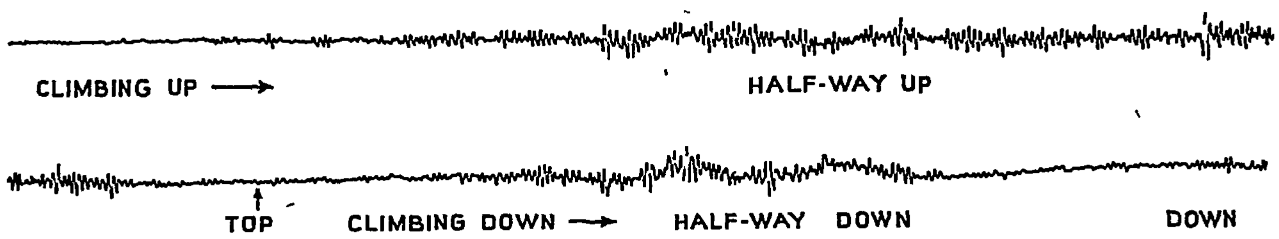

Fig 6—E E G of man climbing up ladder and down again , note β activity when he is half way up and again when he is half way down

It was anticipated that, during exercise, the patient's movements would cause variation in the strength of the signal, owing to changes in the standing wave pattern and to reflections from nearby buildings, lampposts, drain pipes, and other metalwork in the vicinity

Since the wave length allocated is just below two metres (158 75 megacycles per sec), the probability was that such variations would occur at frequencies falling within the low-frequency band required for electroencephalography and interfere with the record Tests proved such fears to be well founded

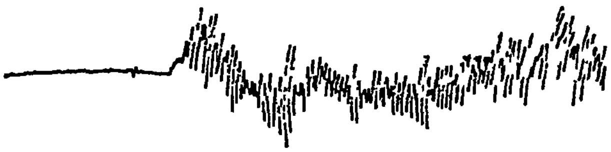

Fig 7—E E G of man climbing ladder who accidentally slipped off rungs and swung from underside of ladder, showing burst of β activity

It was apparent that, if amplitude modulation were applied to the carrier wave, some form of automatic volume control would also be required at the receiving end , and, as a quick response would be necessary, the time constants of such a device would be short enough to permit distortion of lower E E G frequencies But Canadian workers seem to have attempted amplitude modulation (Glasscock and Holter 1949), though later they used frequency modulation (Glasscock and Holter 1952)

Full consideration of alternative methods appeared to indicate that the use of frequency modulation (F M) would offer the greatest chance of success since, owing to limiter action and other reasons a F M receiver is relatively insensitive to amplitude variations, at least within certain limits

For preliminary tests a small F M transmitter was built Seven valves, of indirectly heated subminiature type, were used in a circuit embodying master oscillator and frequency multiplying stages with integral head-amplifier and reactor stages

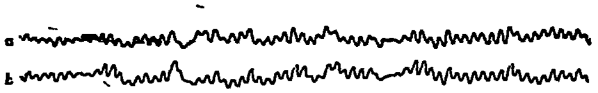

Fig 8—Simultaneous records of E E G from same electrodes in a child aged 12 years *a*, radio , *b*, direct.

The apparatus was fitted in a light copper box measuring 6 × $3^1/_2$ × $3^1/_2$ in and, although it was fairly successful in use, operation was rather difficult owing to frequency drift caused by temperature rise This produced a change in the recording base line necessitating frequent retuning of the receiver

Further tests indicated that if the instrument was to be of clinical value, the use of a free running oscillator could not be justified, and that apparatus built for permanent use would have to be crystal controlled This would ensure a steady basic frequency and permit the use of a crystal controlled receiver, thus eliminating all tuning adjustments during operation, allowing undivided attention to recording

The use of crystal control is not without difficulty, since phase modulation is also implied, leading to a loss of gain equal to 6 db per octave as the frequency of the modulating source is reduced , hence, at frequencies common in E E G work, an inordinate amount of amplification would be required, together with the use of an amplifier having a rising characteristic with reducing frequency

The apparatus in use at present was designed to overcome the difficulties described and has proved to be satisfactory in service

Construction was undertaken in two stages A conventional crystal controlled transmitter, with phase modulation, was built on one chassis, this being bolted to a second and similar chassis carrying the head amplifier and an oscillator capable of reasonably pure output at a frequency of 5 kc per sec

After amplification the E E G wave form is applied to the suppressor grid of the 5 kc oscillator producing an amplitude-modulated tone, which is then coupled, via a suitable transformer, to the control grids of the phase modulator valves

With the head electrodes short circuited the carrier wave will be deviated to a predetermined degree at the rate of 5 kc per sec The arrival of an E E G signal then causes a change in the extent to which the carrier wave is deviated

Fig 9—Apparatus in position

At the receiver the signal is reproduced as a 5 kc tone with the E E G wave form superimposed thereon, and it is a simple matter to demodulate this, to remove the 5 kc component, and to restore the E E G to a form suitable for amplification to the desired level for recording

It will be obvious that, by the addition of other tone generators operating at suitable frequencies, each connected to its own amplifier, a number of channels could be accommodated for the simultaneous transmission of other physiological data—pulse rate, electrocardiogram, &c —the information being extracted at the receiver by passing the output through filter units

As the transmitter was built for test purposes, no attempt was made to achieve minimum size , and, as ordinary valves were used in most of the stages, power-supply requirements are rather heavy Fortunately a new light-weight accumulator of the silver zinc type is now generally available enabling a small rotary convertor for ligation of tributaries, does not heal well. The internal saphenous vein is divided and tied flush with the femoral vein. Its terminal tributaries are sought and divided.

Ligatures are now placed down the leg at the points previously marked. Braided nylon is most suitable for this purpose, because it is non-absorbable and produces no reaction in the tissues. It is softer than monofilamentous nylon and leaves a knot which is in most cases impossible to feel under the skin later. "Six-pound" braided nylon used double is sufficiently strong.

A nick is made in the skin through two companion dots with a tenotome or narrow-ended blade such as the standard no. 11 blade. If the axis of the nick is made along Langer's lines it remains almost invisible, but it may gape if made at right-angles to it. A large $^1/_3$-circle needle—e.g., Bonney's no. 1—is threaded with braided nylon and held on a strong needle-holder (fig. 3). It is now passed, blunt end first, through one nick, under the vein, and out of the other nick, leaving the ligature in its track. It is then reinserted, blunt end first, through the second nick and passed, under the skin but over the vein, to emerge through its original point of entry, from which the two ends of the ligature are now left protruding. These are pulled backwards and forwards once or twice to enable the ligature to slip through the fat close to the vein—if it is not round the vein it will slip out altogether—and tied tightly with three hitches. The ends are cut off with a knife close to the knot. This leaves the skin puckered up, with the knot just below the puncture. If this pucker is now straightened out by stretching the skin, the knot disappears under the skin and the vein resumes its previous position half-way between the two dots. Occasionally a vein may be torn in this process and blood oozes from a puncture; this is controlled with digital pressure and ceases when the next ligature has been tied. The average number of ligatures used per limb in 50 cases was 11, and the largest number 28.

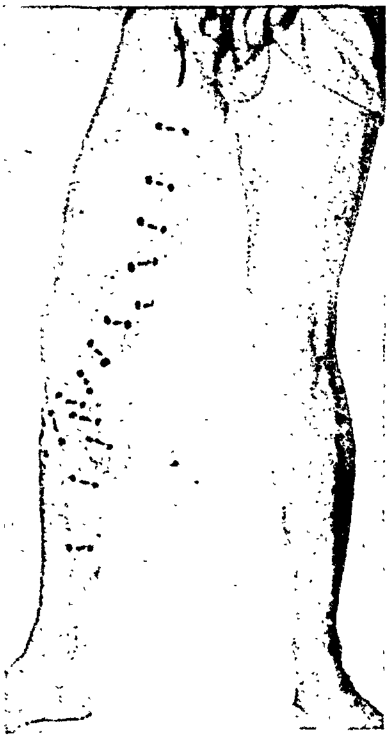

Fig. 1—Infra-red photograph showing method of marking veins. (Varicose anterior femoral cutaneous vein was missed.)

No dressings are needed except in the groin, and a sterile crêpe bandage is applied to the leg.

Results

Two or three days after the operation a clot can be felt in most cases in the isolated segments of the vein between the ligatures. Patients are ambulant from the start and are usually fit to go home the day after operation; but in the present series they were kept in hospital longer for close observation. Occasionally a mild inflammation has developed round a knot but in no case has this been severe, and the great majority of patients have no reaction beyond a vague tenderness, a little local œdema, and perhaps bruising.

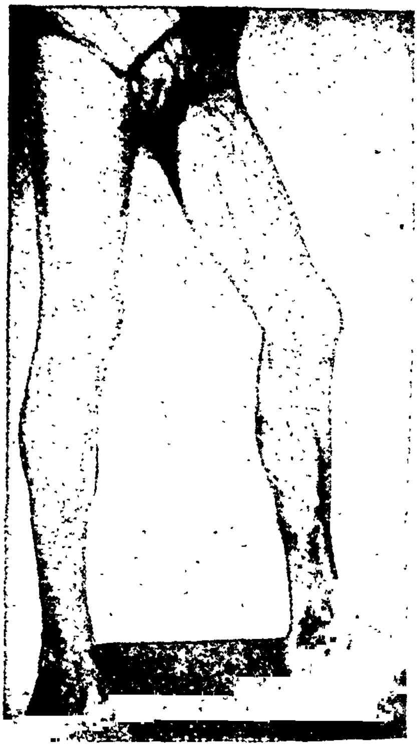

Fig. 2—Pattern of varicose veins elucidated by infra-red photography.

Degree of Obliteration Achieved

In 64% the primary obliteration was regarded as complete without the help of any injections—i.e., all visible varices had disappeared.

In 30% slight varicose veins remained; in half they were negligible, and in half injections were needed to complete the obliteration.

In 6% (3 cases) the varicosities remaining when seen fourteen, thirteen and five months after operation were more than could be obliterated by injections alone. However, the patients were symptomatically relieved, and no further treatment was advised. It must also be said that 2 of the 3 in this group were in the first 5 to be treated; had they appeared later in the series, the veins would have been ligated at more points, perhaps with better results.

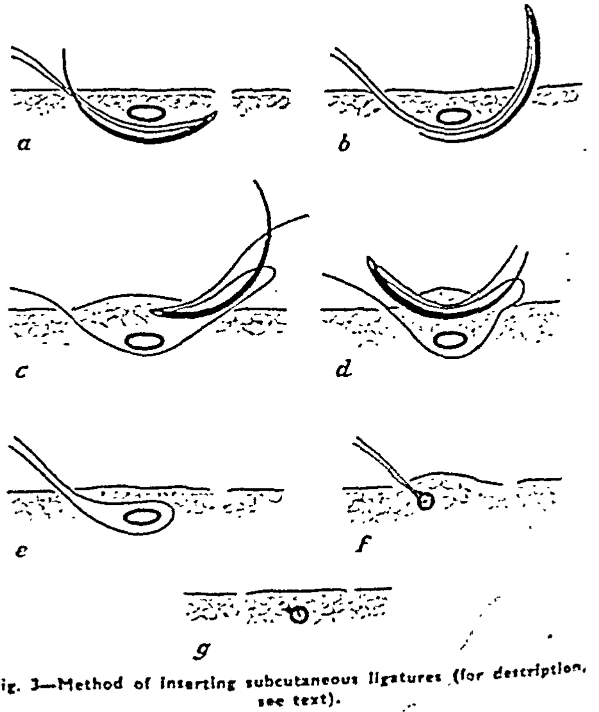

Fig. 3—Method of inserting subcutaneous ligatures (for description, see text).

to be used for high-tension supply, providing a useful recording time of about four hours

Conclusions

We are concerned in this article merely with describing the apparatus and its possible applications, and the tests mentioned are not intended to indicate any conclusions but simply mode of use of the apparatus and possible lines of research with it

The E E G and E C G have so far been mentioned, but, of course, any physiological phenomenon which can be expressed electrically could be studied in the same way with this apparatus—e g, radio tracer work, muscle action potentials, and electrical activity of mucosa No doubt other workers will see applications to their own especial field

There are many uses for this apparatus For example, the phonocardiogram could probably be studied in this way, giving records of the heart sounds during everyday and unrestricted activity Again, the apparatus might be usefully adapted to animal experiments where freedom of movement in the animal is desired

Our thanks are due to Dr A R Grant medical superintendent, Whittingham Hospital, for his most helpful encouragement

Medical Societies

ROYAL SOCIETY OF MEDICINE

Medical Problems in Korea

THE United Services section of the society met on June 10, with Sir Stanford Cade, the president, in the chair

Lieut Colonel R L MARKS described the medical picture in Korea as he had seen it from January, 1952, to January, 1953, when he was commanding a field ambulance in the Commonwealth Division At this time the division held a static position and there was constant patrolling, shelling, and occasional attacks by both sides Enemy air activity was virtually nil and this had influenced forward medical arrangements, particularly evacuation by helicopter There had been a steady trickle of casualties, with some increase after an attack—the greatest number at any one time was 76 The terrain consisted of small hills, scrub, ploughed fields, and paddy fields, the earth roads were dusty in the summer and a sea of mud after rain The front line was reached by travelling in a jeep to company level, and then walking forward in gradually deepening trenches which eventually were about eight feet deep Off these were a number of two to four man dugouts, lit by candles and heated by stoves, in which the men lived

The R M O was situated near battalion headquarters Five miles back was a field ambulance which had two casualty-clearing posts, two miles behind the front-line A field dressing station of 120 beds, with a surgical team and psychiatrist, was ten miles farther back, and on one flank an American M A S H (mobile army surgical hospital), the main centre for surgery, was situated From the M A S H cases were evacuated by train to Seoul, and, if necessary, Commonwealth casualties went by air from Seoul to Kure in Japan and the Americans to Tokyo Cases not likely to recover within three weeks were not kept in Korea The advanced dressing station held cases for up to seven days, and a reserve field ambulance of 100 beds held cases likely to recover within three weeks Because of the static nature of the war and the absence of enemy air activity, the policy was to hold the sick as far forward as possible

With the help of a helicopter, a casualty could be in the hands of the surgeon forty-five minutes after reaching the R M O Some revision of the policy on morphine administration was therefore necessary to prevent cases arriving at the M A S H too heavily drugged Only the R M O gave morphine, and he also gave penicillin and set up dextran drips when needed Medical conditions were mostly seasonal in the winter there were colds, influenza, and a very few cases of frostbite, in summer the main cause of disability was skin diseases and, to a lesser extent, malaria and intestinal infections From May until November there were sporadic cases of hæmorrhagic fever The incidence of gonorrhœa and chancroid was appreciable, and there was some non specific urethritis, but no syphilis Initial diagnosis and treatment (lasting two days) of venereal diseases was carried out at the advanced dressing station, and continuation treatment by the R M O There were few psychiatric casualties Road accidents and burns from stoves accounted for the considerable number of accidental injuries

Major F J INGHAM, introducing the subject of Army health, said that in Korea malaria was endemic, intestinal diseases and tuberculosis were common, and typhus and relapsing fever occurred On the whole, the health of the Army had been good

The climate was extreme, and temperatures lower than 11°F and as high as 95°F were encountered For the winter, special clothing had been provided, including a string vest, combat jacket and trousers, a lined parka coat, special boots, and three pairs of gloves Slacks, a flannel shirt, and ammunition boots were worn in summer The ration per day was 5100 calories in winter and 4500 in summer Water was available at three fixed water points in the divisional area In some areas a tributary of the Imjin river was used The bunkers in which the front line troops lived were infested with rodents which were a menace to the troops 'Warfarin' was successful in controlling the rodents, and D D T powder dealt with the lice D B P and D M P were used as insect repellents Korea was a fairly large reservoir of *Plasmodium vivax*, but the incidence of malaria in the U N Forces was kept low by suppressive proguanil ('Paludrine') (100 mg daily) Civilians were given mepacrine In the Commonwealth division there had been 94 cases of hæmorrhagic fever, with 3 deaths Infection was localised to the forward areas, especially rat infested or swampy regions To protect against the vectors of the disease clothing was impregnated with D B P and antirodent measures were carried out There were not many flies in the forward areas and very few clinical cases of dysentery

Major-General A G HARSANT spoke of the development of the Commonwealth Division in Korea American Headquarters were at Tokyo, where they had their main hospital The Commonwealth hospital was at Kure, where there were 1000 beds The director of medical services for Korea and the consultants in medicine and surgery (all of whom are American) were at Seoul

At the M A S H primary surgery was carried out on battle casualties, who were then evacuated by air or train to Seoul where secondary suture might be carried out Men not retained in Korea were flown from Seoul to Iwakuni by R A A F Dakotas, and thence by train or launch to Kure or, if they needed special surgical treatment, they were flown direct to the American hospital in Tokyo, where there were specialist surgical teams—e g, maxillofacial, thoracic, and neurosurgical teams All neurosurgical cases were treated by the Americans, who had two neurosurgical teams at M A S H.s in Korea and a base unit in Tokyo, and casualties from the whole front were flown by helicopter to one or other of these

In only 6 of 47 patients whose veins have been satisfactorily obliterated was it necessary to inject sclerosants.

Death from Pulmonary Embolus

It must be recorded that there was 1 death from pulmonary embolus. This occurred on the sixth post-operative day. Clotting had taken place in all the varices and had extended from one on the back of the calf, along a communication through the soleus muscle to the posterior tibial vein, and thence to the popliteal and femoral veins.

The possibility of this catastrophe seems inseparable from the intentional clotting of blood in the veins of a patient's legs. Nevertheless it seems to happen more often with some methods than with others, and retrograde injections of large amounts of sclerosants and extensive operations seem to carry the greatest risk. Thus Faxon and Barrow (1938) record 3 pulmonary emboli, 2 of which were fatal, in 228 cases of high ligation with retrograde injection; and Moore and Knapp (1942) reported 2 fatalities from this cause in 88 cases in which excisions had been done.

Whether the present method will be found to carry an undue liability to pulmonary embolus remains to be seen. On theoretical grounds it should not, because the use of sclerosants at operation is avoided and the patients can be fully ambulant immediately after operation. A patient in a hospital ward, though officially ambulant, has nothing to do to keep him on the move, and, though not actually in bed, tends to be equally immobile in an armchair. Probably the best prophylactic against pulmonary embolus is to get the patient home the day after operation.

Effect of the Knots Remaining under Skin

In the first 6 cases strong thread was used for the ligatures; most of these knots have since been discharged, some of them many months after operation, leaving a pigmented mark. In the next 4 cases fine thread was used; this has so far caused no trouble but was given up for nylon, which is very satisfactory. At first monofilamentous nylon was used, but since strong braided nylon has been available it has been preferred. Some of the monofilamentous nylon knots were palpable under the skin, and in 2 cases the patient complained of a knot, which was therefore removed.

Since braided nylon has been used, there has been no trouble. The patient is unaware of the knots which cannot be felt under the skin, and no knots have been spontaneously discharged.

Accidental Ligation of a Cutaneous Nerve

In view of the close relationship of the saphenous nerve to the vein in the leg, it might be expected that it would often be caught in a ligature. This has happened in 4 cases and has produced a small area of anæsthesia above the medial malleolus. Only 1 of these patients volunteered the information; the 3 others had not noticed it or did not think it worth mentioning.

Where large clusters of veins have been found they have been excised, and occasionally the internal saphenous vein is so large and tortuous that it is best excised. With these exceptions it can be said that, coupled with high ligation, multiple subcutaneous ligation has given good early results in 92% of 50 unselected cases, and that in only 14% of these were any subsequent injections needed.

The Question of Recurrence

Recurrences after operation for varicose veins are of two sorts, which might perhaps be termed true and false—the former due to recanalisation, and the latter due to dilatation of veins previously normal. As regards the former, if the knot remains tied tightly round the vein it will not permit blood to pass, even if recanalisation takes place on either side of it. If the veins are divided into short enough segments, this should prevent the points of obstruction from being bypassed by the opening up of collaterals. Perhaps, however, ligatures may partly ulcerate through the veins and, becoming embedded on one side, allow the circulation to be re-established. Recanalisation has been reported after the saphenous vein (Arthur 1944) and the femoral vein (Byrne and O'Neil 1952) have been ligated in continuity, but it is not stated what suture material was used. Recanalisation might be expected if catgut was used —Goldstone (1943) recommended catgut for his subcutaneous ligatures. It seems unlikely that recanalisation will take place when the ligatures are numerous and non-absorbable.

Where recurrence is due to dilatation of veins previously normal and is probably associated with incompetent deep and communicating veins, there can be no method of certain prevention. The best hope of keeping such recurrences at a minimum lies in careful marking and multiplicity of ligation to isolate as many communicators as possible.

Summary and Conclusions

According to McElwee and Maisel (1947) multiple ligature, coupled with high ligation, gives better end-results than do most other methods in common use for the treatment of varicose veins.

For the best results these ligatures need to be numerous.

A method is described by which a vein can be rapidly and (it is hoped) permanently ligated without making an incision. After a formal high ligation this method is used to tie the varicose veins at 2–4in. intervals down the leg.

The method appears to present the following advantages:

(1) It is thorough, in that enough ligatures to obliterate all the varicose veins can usually be made without inflicting a severe operation on the patient.

(2) Patients can walk about on the day after operation without much pain and can be sent home.

(3) The procedure is not complicated by the delayed healing and minor sepsis which may follow incisions in the leg.

(4) It leaves no visible scar.

(5) Further attendances by the patient for injections have been needed in less than a fifth of the cases.

(6) The operation takes much less time than ligation through incision.

The importance of careful marking is emphasised, and for this the assistance of infra-red photography is recommended.

I am grateful to Mr. D. G. C. Tasker and to Mr. R. V. Cooke for allowing me to operate on their cases and for their kindly and critical encouragement. I also want to thank Mr. F. A. Godman, of the department of photography, for the infra-red photographs and for his help.

General Harsant observed that with the present static conditions, air superiority, and freely available helicopter evacuation, casualties could reach the surgeon within an hour or two With such rapid evacuation of casualties, the R M O could become responsible for initiating resuscitation and he could give transfusions of dextran, for example, before the case was evacuated by helicopter Dextran was used in preference to plasma, which carried a risk of hepatitis Blood was collected from local sources by a field-transfusion team for the Commonwealth hospital in Japan, but blood in Korea was freely available from American sources this was for the great part flown from the United States

The body armour that was in use gave efficient protection to the chest and abdomen Its main drawback was its weight Cases of traumatic anuria were sent to a special American research unit in Korea where there was an artificial kidney The Americans were very keen that research should be carried out as far forward as possible, and they had a research team at some of the M A S H s In total war they visualised having a forward research hospital The functions of these teams were to try to solve the problem of the last 1–2% mortality, to provide teaching facilities, and to act as a testing-ground for new ideas

Lieut -Colonel K P Brown described the hæmorrhagic fever first encountered by the U N Forces in the spring of 1951 It had previously appeared among Japanese and Russians There had been a further outbreak in the autumn of 1951, and in all about 1000 cases, mostly American A special M A S H was now dealing with all cases Only about 60 Commonwealth troops had been infected The Japanese view was that the disease was due to a virus, but it was now thought to be caused by a rickettsial-like body The disease was carried by mites and was commonest in scrub and marshy areas The incubation period was two to three weeks The disease was characterised by increased permeability and dilatation of the capillaries and by kidney damage The increased capillary permeability sometimes led to œdema, often in the retroperitoneal region The onset was acute, often with severe headache and chills, and a temperature of 103° There might be severe backache which was very difficult to relieve Considerable thirst was a feature of the early stages, and it had been found that giving too much fluid at this stage increased the tendency to vomit Petechial hæmorrhages began to appear about the third day After this injections and handling of the patients were liable in severe cases to cause echymoses Early diagnosis and treatment appeared to have reduced the liability to severe hæmorrhage later The fever lasted three to five days, ending with rapid lysis Some hypotension usually followed, and sometimes there was severe shock and hæmorrhage All patients had some kidney damage, and albuminuria appeared about the third day Oliguria, which could go on to anuria, followed the febrile stage, but it was not related to the hypotension About the sixth day there was a diuresis that could be so rapid as to require replacement therapy The specific gravity of the urine high in the early stages, fell to 1010 in the oliguric phase and to 1002–1004 during the diuresis After about three months the patient was usually able to concentrate urine to about 1025 The white cell count was low in the early stages but began to rise about the third day, with a slight shift to the left The platelet-count fell by the third or fourth day, and there was a definite increase in the capillary fragility Sometimes there was a characteristic dilatation of the capillaries of the face and sclera, giving a clue to the diagnosis, which was otherwise difficult The mortality-rate was about 5% There was no specific therapy and convalescent serum had been useless in treatment

Suspected cases of hæmorrhagic fever were evacuated Patients with this disease travelled badly and it was the custom to give strong sedatives before evacuation by helicopter Sedation was continued throughout the early stages of the disease Fluid intake was kept on the low side in the early stages, for too much fluid could produce œdema later The artificial kidney, which had been used in anuria and azotæmia, had not been successful in hæmorrhagic fever, but it had been a great help in traumatic anuria Commenting on the similarity between hæmorrhagic fever and scrub typhus, Lieut -Colonel Brown said that it was odd that hæmorrhagic fever should be prevalent in Korea when there had been only 2 cases of scrub typhus

Malaria had not been a great problem, and had been treated with quinine and pamaquin Infective hepatitis was the greatest waster of man-power and there were very large numbers of cases Nothing new had appeared in the treatment All U N troops were protected against Japanese-B encephalitis in 1951 but not thereafter There had been only 2 Commonwealth cases Seoul was the centre of an area where paragonimiasis occurred This was a lung-fluke infection the X-ray appearance of which was similar to that of tuberculosis , but there had been no cases in U N troops

Lieut -General Sir Frederick Harris, director-general, Army Medical Services, said that this campaign was unique in many respects—the absolutely static nature of the war, the complete air superiority of the U N Forces, and the wonderful way in which some twenty nations were working together in complete harmony This cooperation was, he thought, a remarkable achievement and one which would prove to be a great contribution to the peace of the world

The Nature of Virus Multiplication

The Second Symposium of the Society for General Microbiology Editors Sir Paul Fildes, F.R.S , and W E van Heyningen London Cambridge University Press 1953 Pp 320 35*s*

Opinion about recording the proceedings of congresses and symposia is evenly divided Some would like verbatim records of every word spoken or implied, while others would be content to let the hot air drift upwards to the stratosphere and the sound waves to fade gently into the distance The Society for General Microbiology has sensibly compromised in its account of the society s second symposium on the nature of virus multiplication Sir Paul Fildes and Dr van Heyningen are to be congratulated on having edited this " idealised " version of the proceedings in which the contributors to the discussion were given an opportunity to polish and paraphrase their questions and answers before these appeared in print Those who were present at the symposium may have some difficulty in recognising some of the contributions but they will still be able to follow with entertainment and interest the Lwoff-Boyd controversy on prophage, the Fulton-Hoyle dispute on influenza-virus growth, and a host of Bawden-Pirie-isms on every conceivable aspect of virus multiplication This symposium brought together workers with widely different interests and viewpoints, and the discussions covered protein synthesis in general as well as the growth of plant, animal, bacterial and insect viruses This book is therefore more than a record of the proceedings , it is a valuable textbook for those who require to know something of the general aspects of viruses and of their points of similarity and difference

The Pharynx

Abraham R Hollender, M.D , F.A.C.S , emeritus professor of otolaryngology, University of Illinois College of Medicine Chicago Year Book Publishers London Interscience Publishers 1953 Pp 550 110*s*

This new work " dealing with direct and related problems concerning the pharynx " seems to have been produced mainly because of the editor s " own special interest in the various aspects of this important organ,"

ASSESSMENT OF ADRENOCORTICAL ACTIVITY BY ASSAY OF 17-KETOGENIC STEROIDS IN URINE

J. K. NORYMBERSKI
Dr. Ing., Zürich
EMPIRE RHEUMATISM COUNCIL RESEARCH FELLOW

R. D. STUBBS
SENIOR TECHNICIAN

H. F. WEST
M.D. Lond., M.R.C.P.
PHYSICIAN IN CHARGE

SHEFFIELD CENTRE FOR THE INVESTIGATION AND TREATMENT OF RHEUMATIC DISEASES, NETHER EDGE HOSPITAL

WITH the rapidly growing realisation of the physiological significance of adrenocortical hormones, and especially since the introduction of cortisone and A.C.T.H., the need for a reliable method of estimating steroids of adrenocortical origin in the urine has become evident. We hope that the method described here will, at least in part, meet this need.

Steroids isolated from the adrenal cortex have a structural feature that distinguishes them from all other natural steroids; this consists in a particular mode of substitution of the "side-chain" (carbon atoms 17, 20, and 21). The types of this characteristic substitution so far encountered are as follows: (I) 20:21-glycol; (II) 20:21-ketol; (III) 17:20:21-triol; (IV) 17:21-diol-20-one (dihydroxyacetone); (V) 17:20-glycol; (VI) 17:20-ketol. Urinary steroids containing one of these six side-chains can reasonably be assumed to be of adrenocortical origin. The terms (*a*) corticosteroids, (*b*) (adreno)cortical steroids, (*c*) (adreno)cortical hormones and (*d*) corticoids will be used to denote respectively (*a*) steroids of types I–VI, (*b*) corticosteroids known to occur in the adrenal cortex, (*c*) the physiologically active cortical steroids, and (*d*) all substances showing cortical activity by any biological tests.

A well-established method of chemical characterisation of corticosteroids, originally developed in the laboratories of Reichstein and of Mason, consists in the oxidative fission of the side-chain with periodic acid, followed by the identification of volatile products (formaldehyde for types I–IV, acetaldehyde for type V) and/or of the non-volatile products. Of the latter those derived from types III and V are 17-ketosteroids. On the basis of these observations analytical procedures have been developed for the estimation of formaldehydogenic steroids (Lowenstein et al. 1946, Daughaday et al. 1948, Corcoran et al. 1950), acetaldehydogenic steroids (Butler and Marrian 1937, 1938, Cox 1952), and 17-ketogenic steroids (Talbot and Eitingon 1944, Fieser et al. 1944). Within the group of steroids known to occur in urine and in the absence of extraneous interfering material the above methods are rigidly specific. By substituting sodium bismuthate for periodate as oxidising agent, the estimation of 17-ketogenic steroids can be extended to include corticosteroids bearing a dihydroxyacetone side-chain (type IV) (Brooks and Norymberski 1952). Analytical procedures such as the estimation of reducing steroids (types II and IV) (Talbot et al. 1945, Heard and Sobel 1946) and the colour reaction of Porter and Silber (1950) for dihydroxyacetone derivatives (type IV) are less specific. No established analytical procedure for estimating substances of type VI is known to us.

Biological methods for estimating cortical hormones have been reviewed by Dorfman (1950). Of the available tests those based on the deposition of liver glycogen (Venning et al. 1946, Dorfman et al. 1946, Eggleston et al. 1946) are well suited for the quantitative micro-assay of "glucocorticoids." A similarly efficacious bio-assay of "mineralocorticoids" has been described (Tait et al. 1952, Simpson and Tait 1952). The bio-assays are of great importance for the study of substances showing hormonal activity; their application to urine, however, is of limited value, since corticoids are excreted in small quantities and very likely represent only a random fraction of the total urinary corticosteroids.

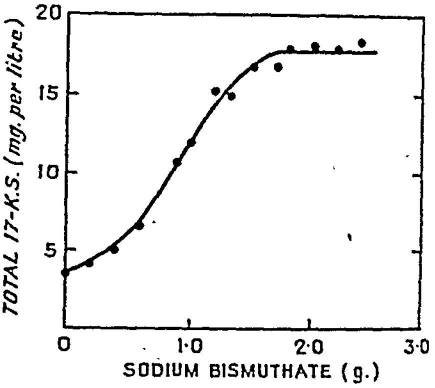

Fig. 1—Relation between quantity of sodium bismuthate and assayed "total 17-K.S."

Paper chromatography of corticosteroids has been described (Burton et al. 1951a, Bush 1952) and applied to urinary extracts (Burton et al. 1951b, Bush et al. 1952). In principle, paper chromatographic techniques offer an ideal means of separating small quantities of complex mixtures into their individual components, which can be further examined by physical or chemical methods. At present, and especially for routine purposes, chromatographic methods have not been sufficiently developed to permit a simple, comprehensive, and quantitative estimation of urinary corticosteroids.

The preparation of urinary extracts suitable for the application of any of the analytical procedures has proved most difficult, for the following reasons. Urinary corticosteroids are excreted mainly in conjugated form, demonstrably so as glucuronides and, by analogy with other urinary steroids, probably also as sulphates. Both types of conjugates are completely hydrolysed by heating with strong mineral acid: this procedure has been found reasonably satisfactory for the extraction and subsequent estimation of, for example, œstrogens, 17-ketosteroids, and pregnanediol, but unfortunately causes the destruction of many corticosteroids. Extraction of untreated urine yields only a small quantity of "free" corticosteroids; at pH1 the extracted amount is substantially increased, and a further increase is achieved by enzymatic hydrolysis with β-glucuronidase. Bayliss (1952) has compared the relative efficacy of the above extraction techniques as assayed by the formaldehydogenic method. It appears from the work of Bayliss and others (for references see Bayliss 1952) that none of the available methods will yield a urinary extract containing the total excreted corticosteroids or a constant fraction thereof which could be considered to reflect adrenocortical activity.

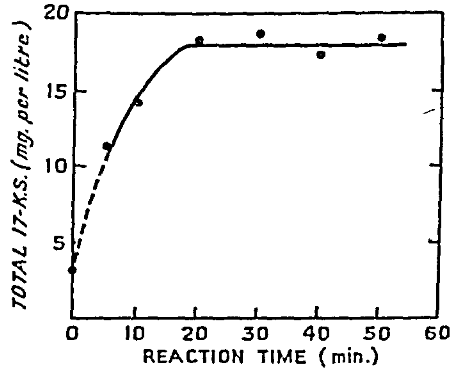

Fig. 2—Relation between reaction time and assayed "total 17-K.S."

Norymberski (1952) has shown that sodium bismuthate converts urinary 17-ketogenic steroids in situ to 17-ketosteroids; the latter can be hydrolysed, extracted, and assayed in the usual manner. Thus one group and it cannot be said to contain anything new Anatomy and physiology are well described, and there are some unusually good chapters—on the blood dyscrasias, on choanal atresia and on abscesses of the pharynx The problems of tonsillectomy and poliomyelitis focal sepsis and tonsillectomy in the allergic child are discussed wisely and at some length But, though carcinoma of the hypopharynx must surely be regarded as truly " pharyngeal "—in its site of origin, its natural history, its behaviour and its management—this highly important subject is dismissed in but a few words in a chapter on pathology Printing and production are excellent

Die körperlichen Behandlungsverfahren in der Psychiatrie

Ein Lehr-und Handbuch Vol I Die Insulinbehandlung Dr MAX MÜLLER, a o Professor für Psychiatrie an der Universität Bern Stuttgart Thieme 1952 Pp 295 DM 36

Prof Max Muller of Berne University, was one of the first to see the spark of genius and the novelty in Sakel's " insulin treatment " of psychoses, which shared the appearance of " foolishness " characteristic (in the words of A N Whitehead) of all really new ideas Müller applied the hypoglycæmic treatment in schizophrenia as early as 1935, and his well-equipped department at Munsingen Mental Hospital was to become a model of organisation and a centre of teaching for psychiatrists from all over the world Among his extensive writings on this and other treatments the present manual of nearly 300 pages deals with insulin treatment only

He attempts to cover the remarkable overgrowth of literature in this field in all languages, reviewing the varied publications critically, although in places not critically enough Of the 70 pages on physiology, pathology, and psychopathology, a good deal refers to work by clinicians without much insight into the physiological and pathological problems, and interests neither the expert nor the physician practising the treatment Similarly, some obsolete oddities could be usefully weeded out of the chapters on technique and its modifications and complications The section on indications, results, and theories is concise, and clearly shows the many debatable points in the mode of operation of the hypoglycæmic treatment and the difficulty in judging its efficacy

The great value of the book lies in its detached and objective attitude, based on an extensive practical experience and on a strong desire to help patients suffering from one of the most serious psychiatric diseases

African Highway

The Battle for Health in Central Africa Sir MALCOLM WATSON, M D, LL D, F R F P S, honorary consultant, Ross Institute of Tropical Hygiene London John Murray 1953 Pp 294 63*s*

IN 1929 the Rhodesian copper mines appointed Sir Malcolm Watson and other members of the staff of the Ross Institute as medical advisers This book sets out to explain how, in a quarter of a century, an unhygienic tropical rural area has been converted into a healthy and flourishing industrial mining district Sir Malcolm is clearly a great believer in the benefits which private enterprise, with sound medical advice, can confer on both European employers and native labour in the tropics, and he is highly suspicious of government schemes In the present uncertainty about the future political development of Central Africa, his great experience of health problems should be invaluable Unfortunately, however, his book is too largely composed of extracts from reports of malariologists, personnel managers, chief medical officers, and field engineers, of financial statements of copper mines and of detailed instructions for building for example, an African hospital and a smoking-pit latrine Much of the material is not recent, and though every reader, whether he has a wide knowledge of tropical life or has never left England, will find many bits and pieces of great interest, the work as a whole lacks continuity of presentation and style, and thus makes difficult reading The 79 excellent and well-chosen photographs are a more vivid testimony to the achieve

Cortisone et corticostimuline (A C T H) en rhumatologie

F COSTE, professeur de Clinique Rhumatologique, J CAYLA, chef de Clinique Rhumatologique, F DELBARRE chef de Laboratoire a la Faculté de Medecine de Paris Paris Masson 1953 Pp 414 Fr 2800

So much has been written about cortisone and corticotrophin that their relevance to the everyday needs of medical practice is perceived with increasing difficulty A comprehensive account of their use in rheumatic disease, where they were first applied, is timely, and Professor Coste and his associates in Paris have produced a useful account of hormone therapy in this field It is based on the study of 460 patients of their own, of whom a third had rheumatoid arthritis, and a fifth had rheumatic fever The indications, dosage, and prognosis are carefully assessed, and particular attention is given to the management of relapses In rheumatoid arthritis, and Still's disease, the use of concomitant gold therapy is described, but the authors are guarded about its value, gold therapy following hormone treatment is not favoured In rheumatic fever corticotrophin is represented as a great advance in treatment, arresting the progress of cardiac damage to a significant extent Professor Coste and his colleagues are aware that " quelques-uns en Angleterre surtout, restent sceptiques," and they make no final judgment, awaiting the results of later follow-up Indeed, in striving to honour impartiality, they have added considerably to the length of their book Methods and cases are described very fully, so that comparison may be made with the American and other European authorities quoted, and a bibliography of 28 pages is witness to diligence in this respect The practical value of the book perhaps suffers through this prolixity, but it is nevertheless a welcome account of this important subject

Advances in Cancer Research

Vol 1 Editors JESSE P GREENSTEIN, National Cancer Institute, U S Public Health Service, Bethesda, Maryland, ALEXANDER HADDOW, M D, D SC, Chester Beatty Research Institute, Royal Cancer Hospital, London New York and London Academic Books 1953 Pp 590 96*s*

THE present volume is the first of a series designed to reflect the " steady and inevitable march of the tides of our knowledge and increasing understanding " of cancer This tidal metaphor is based on the " mysterious and inexplicable ebb and flow of ideas and experimental approaches " to this widely ranging subject First acquaintance with the series shows that it is not intended for the general reader but rather for almost as many experts as there are individual chapters

Included are reviews of electronic configuration and carcinogenesis, epidermal carcinogenesis, the milk agent in the origin of mammary tumours in mice, hormonal aspects of experimental tumorigenesis, properties of the agent of the Rous no 1 sarcoma, applications of radio isotopes to studies of carcinogenesis and tumour metabolism, the carcinogenic aminoazo dyes, the chemistry of cytotoxic alkylating agents, nutrition in relation to cancer, and plasma proteins in cancer All are written by specialists in their own branch, 6 from the U S A and 4 from Britain Most of the contributions are comprehensive and objective, so much so that Reviews would be a more fitting title than Advances Subject and author references and indexes are extensive

The chapter on nutrition in relation to cancer is one that all workers, whatever their specialty, will need to consult One omission here may be regretted—that is the paper, a model of its kind, by J C Drummond in the *Biochemical Journal* (1917)

Those who are new to experimental mammary cancer would be greatly assisted if contributors would make clear whether the work they are referring to was done with or without the milk factor Frequently this was not yet known at the time, by the experimenters themselves Usually it is possible in the reviews in this volume to find out, but as the point is an essential one it might often be more clearly made

The series should be very useful to all who are trying to find their way about the subject r Law" (*British Medical Journal* 1909). This was view of doctors in private practice, and there were ications that at that time many of them would have n prepared to accept a salary for part-time public vice.

The full implementation of either of these proposals ght have prevented the division between the preventive l curative personal services. For the medical staff of ogressive public-health authorities were then extenely engaged in treatment as well as prevention of sease, and had both been sanctioned by Parliament it n hardly be doubted that a unified service would have own up—no doubt with serious effects upon private actice. Alternatively, had general practitioners been ermitted to undertake the work in schools, and later child-welfare clinics, it is also possible that the division ight have been avoided. In this case the attitude of octors to local-authority administration and payment by lary might later have been different from what it was. he Education Act, 1907, and the Maternity and Child Welfare Act, 1918, effected a compromise, by assigng the preventive personal services to public-health uthorities, while curtailing treatment in deference to he wishes of private doctors. This in effect made prevention a public responsibility, and left treatment a private one. The National Health Service Act removed his distinction, but left the machinery of administration of the personal health services essentially unchanged.

Against this background we turn to an examination of the work done at child-welfare clinics today, and to consideration of their future organisation.

Material of Study

We collected our data by investigation of work done at child-welfare clinics in Birmingham (population 1,112,340), and Coseley (an urban district in the adminisstrative county of Stafford, population 34,414).

In Coseley there is only one welfare centre, a well-equipped modern building designed for the purpose. School, antenatal, postnatal, and child-welfare clinics are held in this centre. There are no special sessions for toddlers, and the obstetrician responsible for the combined antenatal and postnatal clinics does not examine infants; consequently the child-welfare sessions, held twice a week, cater for preschool children of all ages. The medical officer who holds these clinics (J. T. A. G.) is also medical officer of health for Coseley. Two qualified health visitors attend each session.

In Birmingham, child-welfare clinics are held at 33 different centres. Of these, 2 (a church hall and a Friends' meeting-house) are in part-time use by the local authority; 31 are full-time child-welfare centres. Of the latter, 13 were designed and built as clinics; the remaining 18 originally served some other purpose (private residence, municipal house, public house) and were adapted by more or less extensive structural alterations for use as children's clinics. Some of these buildings are unsatisfactory, and but for building restrictions during and since the war would have been replaced.

In Coseley all child-welfare services, including immunisation against diphtheria, are provided at the same clinic session. In Birmingham, although all children under 5 years old may attend, the children's clinics are mainly concerned with the supervision of children between 3 and 18 months of age. Mothers with babies under 3 months are encouraged to attend special postnatal clinics, mothers with older children (18 months to 5 years) are given quarterly appointments for toddlers' clinics, and immunisation against diphtheria is offered at special immunisation sessions. The 33 welfare centres provide 64 children's clinics a week, and employ fifteen full-time and twenty-six part-time medical officers, of whom all but four are women. At each session two, occasionally three, health visitors are in attendance.

After a pilot survey conducted at Coseley two record cards were designed. The first was completed by a social worker, who interviewed mothers in reasonable privacy as they arrived at the clinic and recorded their reasons for attending on that particular day. The second card was completed in Coseley by the clinic medical officer (J. T. A. G.), and in Birmingham by one of two medical observers (J. T. A. G. or C. R. L.) who sat in with the clinic medical officer. Data recorded were: sex, age, and birth rank of each child; the reason for medical consultation; and the type of service or services given by the doctor. Direct questioning of the mother was usually unnecessary, since most of the information was available in clinic records or from the mother's conversation with the medical officer. The work of the health visitors at the clinics was not examined in detail.

In the pilot survey the health visitor recorded the reason for attendance at the clinic. This proved unsatisfactory, because health visitors were already fully occupied and because consultations were usually within earshot of those waiting. This part of the inquiry was therefore conducted by a social worker in Birmingham; it was omitted in Coseley.

The Coseley data were collected at 62 consecutive sessions at the child-welfare centre between the end of July, 1951, and the beginning of May, 1952; the Birmingham data were obtained by a single visit, between Feb. 11 and May 12, 1952, to a children's clinic at each of the city's 33 centres. At Coseley the same child was often seen at more than one attendance. In Birmingham, as the postnatal and toddler sessions were excluded, the material is weighted in favour of children between 3 and 18 months of age. Of children referred to medical officers, the proportions under 3 months were 48% and 17% in Coseley and Birmingham respectively. Neither of these features seriously affects the results of our analysis, which is concerned primarily with the work of the clinics and not with the children attending.

Results

REASONS FOR ATTENDING THE CLINIC

The reasons given for attending were to have the child weighed, to obtain advice from the health visitor or doctor on some specific problem, and to purchase proprietary foods (table I). On the recommendation of the medical officer proprietary foods are available at wholesale prices, and whatever the official view mothers evidently consider this function of the clinic important. Nearly half of them (44%) gave food purchase as a reason for attending, 19% gave it as the only reason, and 15% had not brought the child with them. (In principle mothers are not allowed to buy food unless the child has been seen within the preceding fortnight.) In addition, an average of 51 mothers per clinic session attended for the sole purpose of shopping at the branch food offices established at 26 of the 33 Birmingham centres. These mothers, who came without children, did not enter the clinic proper, and are excluded from all tables.

REASONS FOR REFERRING CHILDREN TO THE MEDICAL OFFICER

The proportions of children referred by health visitors to the medical officers were 39% and 27% in Birmingham and Coseley respectively (table II); the average numbers

TABLE I—REASONS GIVEN BY BIRMINGHAM MOTHERS FOR ATTENDING CLINIC

Mothers accompanied by children					Mothers not accompanied by children	
Routine weighing	Specific advice	Purchase of proprietary foods			Purchase of proprietary foods	Total
		Only	And routine weighing	And specific advice		
39·4% (*650*)	16·9% (*278*)	4·3% (*71*)	21·2% (*349*)	3·3% (*55*)	14·9% (*245*)	100% (*1648*)

TABLE II—PROPORTION OF CHILDREN REFERRED BY HEALTH VISITORS TO THE MEDICAL OFFICER

—	Children referred to M O	Children not referred to M O	Total
Birmingham	39 4% (*553*)	60 6% (*850*)	100% (*1403*)
Coseley	26 8% (*868*)*	73 2% (*2367*)	100% (*3235*)

*Of 868 children referred to the Coseley medical officer 325 immunised against diphtheria have been excluded from subsequent tables

of children attending per session were 43 and 52 and the average numbers seen by medical officers 17 and 14 Table III gives reasons for referring children to the doctors (Children referred for immunisation in Coseley have been excluded) About a third had been sent for routine examination In both local authorities a child paying its first visit to a clinic is automatically referred for medical inspection, but after the first visit practice differs in Coseley children see the doctor again only by special request, in Birmingham they are referred for medical supervision about once in three months There is a considerable difference in the proportions seen at the request of health visitors (Birmingham 19%, Coseley 1%), which suggests that part of the work done in Birmingham by medical officers was performed in Coseley by health visitors

More than 40% of the children medically examined had been sent to the medical officer at the request of the mother Since the National Health Service Act has removed the economic reason, we asked why these mothers chose to consult the clinic medical officer rather than their own general practitioner (table IV) More than 40% of the mothers had not considered the possibility of consulting their own doctor A further 10% had attended the clinic to collect food or to have the child weighed, and, having some minor problem, " thought they might as well see the doctor there about it " The remainder (almost half) gave reasons suggesting dissatisfaction with their general-practitioner service the surgery was too far away, a crowded surgery was no place for a child, afternoon consultation was more convenient, or the doctor was abrupt, rude, or too busy to make even a cursory examination

WORK OF THE CLINIC MEDICAL OFFICER

Table V gives details of the work done by clinic medical officers Some children (73 and 71 in Birmingham and Coseley respectively) had more than one service but we have considered only the more important service

Routine Examination —About 10% of the work done by the medical officers consisted in routine examination of children so healthy and well-cared for that no advice was considered necessary That is to say, 120 of the 338 children submitted for routine examination (table III) were thought to need no service of any kind

Reassurance —About 16% of children had minor ailments—sometimes real, sometimes imaginary—for which no treatment and little specific advice was needed (coryza, transient skin conditions, and minor general complaints)

Advice —About a third of the mothers (34 0% in Birmingham and 29 8% in Coseley) were advised about the feeding and general management of their Table VI gives details of the kind of feeding problem a which advice was sought—e g , weaning, breast fe or complementary feeding Under " general ment " (table V) are included instructions napkin hygiene, clothing, physical activity, and b bladder, and sleeping habits Also included " advice " in table V are cases in which the medical issued certificates or advised about priorities Birmingham and Coseley 1 8% and 7 7% respectiv were of this type In both local-authority areas chil were certified as fit to enter day or residential nurse and notes were written to expedite hospital admis In Coseley the doctor, as medical officer of health, also concerned with the rehousing of families for med reasons, and with the issue of free infant foods necessitous families

TABLE III—REASONS FOR REFERRING CHILDREN TO THE MEDICAL OFFICER

—	Routine examination		Specific request by				T
	First visit	Quarterly supervision	Clinic M O	Health visitor	Mother	Hospital or G P	
Birmingham	11 6% (*64*)	16 3% (*90*)	11 2% (*62*)	19 2% (*106*)	41 4% (*229*)	0 4% (*2*)	
Coseley	33 9% (*184*)		17 1% (*93*)	0 7% (*4*)	46 8% (*254*)	1 5% (*8*)	

Treatment at Clinic —In Birmingham about a (22 1%) and in Coseley a third (33 7%) of children treated at the clinic Table VII shows the conditions with—e g , umbilical hernia or polyp, phimosis, respiratory infections, and napkin and teething ras The official attitude towards treatment in child-wel clinics has always been that a child needing anyt more than the most trivial attention should be refe to his own doctor, and clinics in general stock onl few simple medicaments

Referral —Finally, 16 8% and 9 4% of Birmingh and Coseley children respectively were referred elsew for conditions similar to those met in the consulting r of the general practitioner—e g , p cough, diarrhœa and vomiting, media, and cellulitis (table VIII) Most of these pati (72% in Birmingham, and 92% in Coseley) were refe to their general practitioner, a few were sent direct hospital, or to local authority dental or remedial cli

Discussion

We may summarise the results of the foreg analysis of the work of child-welfare clinics as foll

In Birmingham, on the average 101 mothers atten each session, of whom 51 bought food at the branch f office, and 50 entered the clinic proper Of the 50 entered the clinic, 7 attended without the child obtain priority foods 43 attended with the child, whom 20 came to have it weighed, 8 to get specific adv and 15 to obtain priority foods Of the 15 who came foods, 11 wished also to have the child weighed, an to have advice about its management It is clear that whatever the official view of the clinic's function, the distribution of cheap food is still an important incentive for attendance

TABLE IV—REASONS GIVEN BY MOTHERS FOR NOT CONSULTING A GENERAL PRACTITIONER

—	Not considered by mother	Attending clinic for other reasons	Clinic hours or location more convenient	G P too busy	Advice wanted about need for consultation	No confidence in G P	Other and unspecified	Total
Birmingham	44 1% (*101*)	11 4% (*26*)	9·2% (*21*)	5 2% (*12*)	7 4% (*17*)	21 8% (*50*)*	0 9% (*2*)	100% ([illegible])
Coseley	40 6% (*103*)	10 6% (*27*)	7 9% (*20*)	5 9% (*15*)	11 8% (*30*)	21 7% (*55*)*	1 6% (*4*)	100% ([illegible])

* 9 Birmingham and 3 Coseley mothers had already consulted their general practitioners but were not satisfied with his advice

THE LANCET

LONDON: SATURDAY, JUNE 27, 1953

Cardiac Catheterisation

Some twelve years have passed since Cournand and Ranges[1] began to describe results of right atrial catheterisation; and it is nearly a decade since McMichael and Sharpey-Schafer[2] began to report on the application of the procedure in this country. Regarded at first with some suspicion and reserve, cardiac catheterisation quickly found a very important place in the selection of cases of cyanotic congenital heart-disease for operation. Every cardiac centre where surgery is undertaken now has a laboratory for catheterisation and allied procedures, such as angiocardiography,[3] and for related studies of pulmonary function. The old cardiologist with his quiet and mild stethoscopic and electrocardiographic studies has been replaced by a highly organised team surrounded by complex and expensive laboratory equipment. The cardiac laboratory is a hive of industry; here clinical investigation and research go hand in hand, and every obscure cardiac problem is illuminated—or sometimes made more difficult—by a mass of hæmodynamic data. Technical advances have been applied with alacrity. Instantaneous optical and other similar pressure-recording devices are now in routine use; and in cases of congenital heart-disease angiocardiography with special radiographic equipment is undertaken at the same time as catheterisation. Recently oximeters have been developed which, by transillumination of the ear on to a sensitive photocell, provide immediate information about the oxygen content of the blood, or even a continuous record of its changes. Moreover, the oximeter can be readily used to study the passage through the circulation of innocuous blue dyes after their rapid injection either into a peripheral vein or through a catheter into the heart itself. By this means intracardiac shunts may be recognised; and, where the heart is of normal configuration, the time of passage of the dye permits the estimation of intrathoracic blood-volume (mainly in the lungs).[4]

The place of cardiac catheterisation in congenital heart-disease and in other diagnostic cardiac problems is well reviewed in a Mayo Clinic symposium.[5] By intensive investigation of various types of pressure-recording systems a strain-gauge system has been found to give the most accurate reading of pressures and greatest freedom from artefacts. The report emphasises the value of catheterisation studies combined with intracardiac injection of dye. In the presence of a right-to-left intracardiac shunt, dye appears in the systemic vessels much more rapidly than dye passing through the lungs. Study of the curves of dye concentration may thus be of great value in locating the site of a shunt. Necropsy studies of hearts previously catheterised showed, however, that data from catheterisation could be confusing or even misleading. For example, slight patency of a foramen ovale may sometimes be important, and yet difficult or impossible to recognise by catheterisation.

Cardiac catheterisation has won an unassailable place in relation to these special problems of cardiac surgery, but knowledge of its risks has also increased. In the earlier years most investigators were satisfied with pressure measurements and blood samples from the right atrium, and little harm seems to have resulted.[6] Gentle passage of the catheter along ever-widening veins into the middle of a roomy right atrium need cause no trauma. But when the operator decides to probe beyond this, round the bend of the right ventricle and pulmonary artery and into as many accessible chambers as possible, in deformed and diseased hearts, it is not surprising that trouble may arise. The Mayo Clinic pathologists saw subendocardial hæmorrhage in 2 of 28 catheterised hearts in cases where the patient had died from other causes. Limited local thromboses in the arm veins and transient arrhythmias during catheterisation are common. The Mayo Clinic workers report 2 deaths and 4 cases of more persistent arrhythmia in 474 catheterisations. On the other hand, 3 patients died while awaiting the investigation, and other recorded deaths have usually been in seriously ill patients. McMichael and Mounsey[7] have recorded precordial pain and collapse, probably resulting from passage of the catheter into the coronary sinus. Hebert et al.[8] report a hæmatoma at the mouth of the coronary sinus in one case and hæmopericardium in another. Pyrogenic reactions are difficult to avoid completely, and in seriously ill patients these can be lethal; while occasionally thrombotic complications may lead to serious embolism. Lenégre puts the mortality from catheterisation at 0·7% (7 in 973), but resulting morbidity may be higher. The American Heart Association has appointed a committee to report on catheterisation and make recommendations, and its report will be awaited with interest. Meanwhile, all concerned with this type of investigation will no doubt apply it with full knowledge of both its advantages and its potentially harmful consequences. Technique must be rigorous, with careful precautions against the known complications; and correct indications should be accepted Discrimination is needed, because only a small proportion of cardiac patients require study by catheterisation. The reasons should be precise, agreed by responsible senior staff in consultation, and explained to the patient, who should give consent; and the cardiologist in charge of the patient should himself be responsible for the conduct of the catheter study. Where cardiac-output studies alone will suffice, catheterisation should not go beyond the right atrium, for the minor inaccuracies of mixed venous-blood samples from this

difficult in the past year to get a true picture of how this expenditure was going, but the drug bill had climbed from £31½ million in 1949–50 to an estimated figure of £46½ million in 1953–54. There had been a steady increase in the total number of prescriptions dispensed, and a rise in their average cost from 2s 9d in the first year to 4s 2d now. Much of the rise in cost was due to the introduction of new and valuable, though expensive drugs, and there had been a rise in ingredient prices until this year, although, again it was only fair to say that some of the most important drugs especially the antibiotics, had fallen substantially in price.

Under National Health Insurance in 1947–48, 7% of prescriptions dispensed were proprietary, in 1949–50 the figure rose to 15%, in 1950 to 18%, in 1951 to 23%, and in 1952 to 26%. There was no sign of a reversal of that tendency. The 1952 figure of 26% represented 52% of the ingredient cost and 44½% of the total cost. Everyone knew of examples in this particular field. The attention of the country—and of practitioners through *Prescribers' Notes*—had been drawn to a proprietary slimming preparation which if prescribed by its standard name would have produced a saving of £242,000 in 1951. The right way to look on that potential saving of nearly a quarter of a million pounds was to think what could have been done with the money.

"If that quarter of a million has gone—I don't suggest wholly—but partly unnecessarily, then it means that some hospitals have gone short and that I have not been able to authorise, as I would like to have done, certain improvements in many of the parts of the service that you all know need improving."

There were proprietary tablets which had as their main ingredients aspirin, phenacetin, and codeine which cost 6s 3½d for 50, whereas the same number of tablets of the comparable standard preparation cost 2s 11d. A review in the *British Medical Journal* showed that certain asthma inhalant preparations cost four or six times the standard equivalent, "and you have been told, not by the Ministry, but by your own organisation, that there is little or nothing to choose in merit between them." It was true that many preparations had no exact official equivalent—that many preparations, particularly the antibiotics, were in fact only made up in proprietary forms. It was also true that a most important contribution to our exports—not less than £30 million in a year—was made by the pharmaceutical industry. It was, true, too, that they devoted a good deal of money to research, from at least some of which all the people in this country might well benefit. But this was not true of all preparations and it was not true of all firms.

"It is here then that, quite frankly, I want your help. I cannot tackle this wholly by myself, and I do not pretend that I can. You know the way in which doctors can help. I know perfectly well it is easier to say these things than to do them, but we can make careful use of the *National Formulary* preparations. We can by referring to the two tables of proprietary preparations in the formulary—which shows those for which an equivalent standard preparation is available—decide whether they are of substantially the same therapeutic effect as perhaps another preparation which could be prescribed. I think it is important to stress here that while many formulary preparations are cheaper, there is no reason to regard them, as I am sure you do not on that account, as being inferior. They were recommended by medical and pharmaceutical experts quite independently of my Ministry; they conform, as you know, to the standards laid down in the *British Pharmacopœia* or the *B.P.C.* Again, I think you can help by satisfying yourselves, before prescribing a proprietary preparation that is not included in the two formulary lists that there are adequate grounds for believing that its therapeutic value is superior; and finally—and again this is easier no doubt to say than to do—by resisting pressure from patients to prescribe particular preparations which they have had recommended to them or about which they have read in technical or semi-technical or lay papers."

"You all receive copies of the *Prescribers' Notes* and I intend to issue to you a price list of preparations and proprietary preparations listed in the formulary which are frequently prescribed. We have had a clear lead from Sir Henry Cohen's committee, and when the official classification of proprietary preparations has been completed, which will be in a very short time, I propose to circulate this to you all. Finally, as I told the House of Commons, I must myself by cost investigations satisfy myself that the prices being charged are themselves not excessive. In my desire to help there I am setting on foot as many investigations as I can undertake into selected preparations in the categories which Sir Henry Cohen's committee advise me should be prescribable provided a satisfactory price agreement can be reached."

Nothing whatever in what he had said, or in what he intended infringed in any way on the doctor's right to prescribe.

HOSPITAL AND GENERAL PRACTITIONER

Among the things that we wanted to achieve, said the Minister, was that more patients were treated in their own homes and on the whole fewer in hospital.

"I do not put that forward on economic grounds, although that is certainly a factor, because hospital treatment works out at £700 a year, whereas domiciliary treatment is a quarter or less of that figure. But many patients would, in fact, benefit greatly if they could be treated in their own familiar surroundings without the disturbance and stress and anxiety of removal to a hospital. If the cost of the hospital service continues to grow, as it shows every sign of doing, it is inevitably going to absorb more and more of the money that can be set aside for the health service. So we must try, if we can, to lighten the load on the hospitals provided that can be done without any detriment to the patient."

The treatment of a greater variety of patients at home could add enormously to the value and interest of the work of the general practitioner. Mr Macleod regarded direct consultation between consultant and practitioner as of the first importance, and he would like to see here and there more advantage taken by the practitioner of the opportunity of meeting the consultant in domiciliary consultation in the patient's home. It was also of first importance that the practitioner should have direct access, not of charity but of right, to the X-ray and pathological services.

"He should be told, too, and he should be told at once, when his patient leaves hospital, and when he refers a patient for consultation he should receive the considered opinion always of a senior member of the staff. Then he should always be made welcome in the hospital no matter whether he is accompanying a consultant on his rounds or visiting a patient or just dropping in—he should be part, in the fullest sense, of the hospital service in his particular area. Now this is common practice in many places but there are many of you who know that this sort of welcome without jealousy is not always extended to the G.P. in every hospital."

As regards the liaison between the practitioner and the local health authority, particularly in preventive work, he had been struck by the differences apparent in different areas. In some places—usually where there was an able and energetic medical officer of health—there was the closest contact between health visitors and practitioners, but in others the partnership should be closer. Many people felt that too many cooks were concerned with the welfare of the patient, and feared that the practitioner might be crowded out; but there was no danger of that provided he was recognised to be the clinical head of the whole team—"the clinical leader of all the domiciliary health services, bewildering as they may be in their variety, which are provided for people in their homes."

SOLVING THE PROBLEMS

We were engaged in a magnificent experiment in social medicine, said Mr Macleod, and it must not be strangled by too much administration or central direction. Only situation are more than counterbalanced by considerations of the patient's safety and well-being. Where other methods of circulatory study, such as the dye techniques, will give sufficient information they should be used in preference to cardiac catheterisation. The presence of expensive equipment occupying valuable space should not determine the type of study pursued. Otherwise, man becomes the slave of his machines.

Nursing Problems in the Provinces

In our time the training of nurses, though still largely practical, has had a growing academic content; and many have suggested that this trend is becoming too pronounced. Hospitals which find it difficult to get enough recruits of a suitable type are especially apt to complain that the syllabus is too exacting; and indeed, from the administrator's point of view, the obstacles it can present are often serious. The hospital management committee of the Luton and Hitchin group no. 2 have lately approved a report[1] from Mr. R. E. LINGARD, their secretary, which speaks strongly on the subject.

Recruitment to nursing has improved very much in recent years. In 1947 there were 46,655 nurses in training; in 1951 there were 58,270. Since then the figures have levelled off, and it is probable that recruitment has reached its peak. Nevertheless, in Mr. LINGARD's opinion, expansion would still have been possible in "progressive schools and hospitals" but for three changes—one already in action and two still in prospect—in the regulations of the General Nursing Council. On Aug. 1 last year, the G.N.C. fixed the age of entry to nursing training at 18—a rule which we have long advocated and fully support, though there is no doubt that it has placed many hospitals in temporary staffing difficulties. The council have also drawn up a new syllabus, to come into force in January of next year, which increases the time spent by the student nurse in the classroom; and have announced their intention, at a date not yet specified, of raising the educational standard required of entrants. Mr. LINGARD believes that a year ago, before the new age of entry was enforced, the only reason why hospitals in his group could not enlarge their nursing staffs was lack of residential accommodation. For the past eight months, however, recruitment in this group has not kept pace with losses. This he attributes largely to the raising of the age of entry from $17^1/_2$ to 18. He argues that if girls of $17^1/_2$ formed 20% of the hospitals' intake in the past, this change of policy means a permanent reduction of 3000–4000 in the number of students working in hospitals. But a girl who is not accepted for training at $17^1/_2$ does not dissolve into air: she is usually still there six months later, and her wish to nurse may well have survived the interval, particularly if she is able to take a pre-nursing course and to complete part I of her preliminary examination before she enters hospital. It was inevitable that recruitment to hospitals formerly taking girls at $17^1/_2$ should drop seriously during the first six months after enforcement of the new rule; but we must wait for the figures for the second six months before we can say whether recruitment has been permanently injured.

Like the rest of us, Mr. LINGARD has been much impressed by the finding of the Nuffield Job-Analysis Team[2] that three-quarters of the time spent on nursing duties in the wards is contributed by student nurses. So long as this is the case, he argues, and so long as the greater part of the student nurse's time is spent in giving service to the hospital, as distinct from receiving tuition, her real status is something between that of an apprentice and one serving articles, and not that of a student. He therefore regards with misgiving any measures which lead "to an undue increase in the time spent in classrooms, with a consequential loss in the time spent in wards." It is easy to understand his anxiety—the anxiety of the administrator who has to see that beds are staffed and patients nursed. But it would be unfortunate if, at a time when all other countries are steadily advancing the standard of training and status of their nurses, we—the pioneers—reduced ours to the level of so many pairs of hands. A nurse fit to take responsibility in modern wards cannot be bred by the *practice* of ward work alone: she must have a theoretical training, and the time at present allowed to her for this purpose is small.

It is true, of course, that a nurse engaged in the routine tasks required to keep her patients comfortable does not necessarily need a high standard of academic ability or training. But that is why the grade of State-enrolled assistant nurses (S.E.A.N.) was set up—to keep within the nursing team the girl who has no academic gifts but has a natural bent for nursing. The nursing orderly, too, can be used in the team to supplement the nursing staff. Thus hospitals with recruitment difficulties are now in a position to consider a new staffing structure. If they cannot attract enough entrants of adequate educational standard they can either supplement their students with orderlies, or turn over to the training of S.E.A.N.S instead of S.R.N.S. Unfortunately, such a change in the type of training offered is felt to entail a loss of face. It also means, for the matron, a financial loss, for matrons of S.E.A.N. training-schools receive a slightly lower rate of pay than matrons of schools training S.R.N.S. This pointless distinction should surely be obliterated; and it is to be hoped that the nursing profession will themselves get that done. If the G.N.C. do raise the educational standard required of entrants it is probable that many hospitals will find it convenient to make this change. The proposed standard is still under consideration: it will probably be that reached by the ordinary girl leaving a secondary (grammar or modern) school at the age of 15.

We are looking towards a new structure in nursing, built on the notion of the nursing team. There will be room in it for women of high academic, technical, and administrative ability; for responsible women who combine gifts for ward management, clinical nursing, and the teaching of juniors; for comfortable competent bedside nurses with no academic pretensions; for intelligent orderlies attracted by an interesting job: and for students in training for either the register or the roll. It has always been a profession offering scope for many talents, but now the opportunities are expanding horizontally as well as vertically.

because the necessities of the financial position at the moment forced him to do so did he keep the reins firmly in his hands All his instincts were towards giving greater and greater freedom to those who really worked the health service, and everything he did would be directed to that end however crabwise his movements appeared to be

"I don't assume, when proposals are put to me by the medical, dental, or nursing profession that they are necessarily biased or necessarily wrong On the other hand, I don't work on the assumption that you are necessarily right either But I would like to say this I want now, as I have always done since I became Minister, to seek your help and the help of all the other professions in the National Health Service This is not a job that the Minister can do alone, or the department alone, nor the doctors, or any of the other professions It is essentially a matter in which we must work together, it is essentially something in which I need your help, and I am very ready to come to you for advice Any help I can give is at your disposal, but it is only in partnership together that we are going to solve these problems and achieve the true potentiality of our National Health Service"

Dr **TALBOT ROGERS**, chairman of the General Medical Services Committee, in thanking the Minister for his address, referred to discussions with the Ministry during the past few years on the mounting cost of the drug bill The committee, he said, would do all it could to assist in stabilising the cost of the pharmaceutical service provided this was not incompatible with the essential needs of the patient

Public Health

AN EXPLOSIVE OUTBREAK OF FOOD-POISONING CAUSED BY SALMONELLA DUBLIN

A M McCALL
M R C S, D P H
MEDICAL OFFICER, CHARD BOROUGH AND RURAL DISTRICTS, SOMERSET

ON Sept 25, 1952, an outbreak of food-poisoning caused by *Salmonella dublin* affected a large number of children in schools in Chard and the surrounding rural districts, and also a smaller number of adults mainly resident in the borough of Chard The outbreak was brought to my notice soon after the schools had assembled on Friday, Sept 26 As school children were involved, a rapid analysis of a large number of cases was possible, and evidence pointed strongly to milk as the most likely vehicle of infection The milk to the school originated on a farm supplying tuberculin tested (T T) milk, most of which was consumed at this and other schools, the remainder being delivered to the public On investigation of the herd concerned it was found that one cow had been taken ill and isolated on Sept 23 Within twenty-four hours of the start of investigation *S dublin* had been isolated from milk from the cow and from fæces of 2 of the victims

NOTIFICATION

On the morning of Sept 26 the acting head teacher of a large school in Chard found that about 100 children were absent and several in school were complaining of sickness and diarrhœa He immediately telephoned the health department

All the general practitioners working in the area were at once informed of the outbreak and asked to send any specimens of vomit and/or fæces to the Public Health Laboratory as soon as possible The director of the laboratory was also informed

Only 1 notification was received from a general practitioner Some practitioners, however, sent specimens to the Public Health Laboratory, and copies of the reports on these were sent to the health department

METHOD OF INVESTIGATION

The first information came from a secondary modern school Many of the children came from outlying villages and the head teacher was asked to make a list of absentees and their addresses, and to state whether they took school meals and/or school milk, or neither Other schools which could be approached on the telephone were asked to do likewise These lists were collected, and a rapid analysis pointed towards school milk, but it was found later that there were some cases of illness among children and teachers who had neither milk nor meals in school and some who had meals only

All the schools approached received their milk from the same source The supply was known to be T T non pasteurised milk, and the bottling and retail department of the suppliers was next visited The routine was for the bulk supply from the herd for the day—i e, morning and evening milk—to arrive in the bottling department in the late afternoon, when it was bottled and put in the refrigerator overnight The milk was sent out at 7 30 next morning The bottling machinery and refrigerator were all in good order, the methods of cleaning and sterilisation were satisfactory, and no member of the staff had been ill or had any symptoms of disease Of the 150 gallons of T T milk being handled daily 90 gallons went to schools

Fortunately all the milk came from one herd, and the farm was next visited The farm building and milking stalls were of modern type with a good water supply and concrete yards which were all in good condition Electrical milking apparatus was used The cows being milked were in good health, but it was discovered that one cow (Ladybird) had been isolated with mastitis on Sept 23 She was isolated about 11 A M, therefore it was possible that milk from her in the morning had got into the bulk supply distributed on Sept 24 A sample of her milk was taken and, together with a bottle thought to be left over from Sept 24, sent to the Public Health Laboratory The veterinary surgeon looking after Ladybird was informed of the outbreak He immediately examined her and expressed the opinion that she now presented a picture of a salmonella infection Immediate arrangements were made for all further milk from this farm to be heat-treated, and general practitioners were informed that a salmonella was a very likely cause of the outbreak This part of the investigation was completed by midday

By next morning the laboratory had isolated *S dublin* from the cow's milk and from the fæces of 2 patients The general practitioners were informed of this result and of the sensitivity of this strain of *S dublin* to chloramphenicol All the affected schools were informed of the cause of the outbreak and warned of the danger of secondarily infected cases The need for strict personal hygiene and extra cleaning of all cloakrooms was emphasised

SYMPTOMS

The order in which the symptoms presented varied All the patients had nausea, often but not always followed by vomiting The patients who did not vomit appeared to have severe abdominal pain, but so did many who also vomited A fairly common symptom in the early stages was severe headache, mainly frontal, with some giddiness This type of headache has been noted previously, and *S dublin* has been found to be the causal organism of meningitis (Guthrie and Montgomery 1939) Extreme pallor was a striking sign Temperatures varied from 99 5°F to as high as 105°F, but most were 100°–102°F The length of illness varied, but most of the patients recovered in three or four days There were no deaths

Treatment of Renal Tuberculosis

THE treatment of renal tuberculosis has been modified but not revolutionised by antibiotics. These new weapons, which are still being developed, are likely to play an increasingly effective part in the war against tuberculosis; but they have certainly not rendered obsolete the older weapons—constitutional treatment and surgery. They have indeed had the opposite effect by showing up the continuing need for constitutional treatment and the advantages of surgery. As COSBIE ROSS and his colleagues[1] remark, these three weapons are complementary, and surgery is only an incident in the course of treatment. The crude doctrine of Alberran, epitomised in the equation *tuberculose rénale=néphrectomie immédiate*, is based on a false conception of the disease by which the tuberculous process was regarded as starting as a solitary focus in one kidney and spreading from there to the rest of the renal tract, including the opposite kidney. It is far more probable that the disease starts in scattered hæmatogenous foci in both kidneys and that the macroscopic "solitary" focus is merely one of these lesions which has developed, the others having healed or become quiescent. In these circumstances nephrectomy for tuberculosis cannot be viewed as a radical operation, and the concept of *néphrectomie immédiate* gives place to that of *néphrectomie opportune*, in which the operation is delayed until constitutional measures and antibiotics have brought the infection as far as possible under control.

There is evidence that streptomycin can heal the small closed parenchymatous focus, but not the established caseocavernous lesion.[2] Fibrosis is a feature of the untreated tuberculous lesion, making an avascular wall around the lesion which hinders the access of blood-borne therapeutic agents. Streptomycin, by increasing this fibrosis, impedes its own action. In urinary tuberculosis the contraction of such fibrous tissue has other untoward effects, such as ureteric obstruction and vesical contracture. Altogether this action of streptomycin must be reckoned a serious defect, and it is encouraging to see the results of histological studies of the effects of isoniazid on tuberculous renal lesions, lately described in these columns by Dr. DICK.[3] One of the most striking findings was the absence of fibrosis in the more recent lesions in cases treated with isoniazid only. Even the old fibrotic lesions showed revascularisation, in striking contrast to cases treated with streptomycin and to untreated cases. Moreover isoniazid seemed to arrest caseation and even to promote absorption of caseated material. Thus isoniazid put the tuberculous process, so to speak, into reverse; but unfortunately this improvement was not maintained after three months' treatment in cavities and in open lesions of the calyces and pelvis; here there were signs of reactivation. These histological findings correspond with the clinical impression that the improvement brought about in the first three to six weeks of isoniazid treatment is not maintained. According to in-vitro bacteriological evidence tubercle bacilli resistant to isoniazid quickly appear; but this complication can be retarded by combining isoniazid with streptomycin. Moreover DICK found evidence that isoniazid reversed some of the fibrotic changes even in chronic lesions previously treated with streptomycin. Thus it seems that these two drugs are to some extent complementary.

Nephrectomy is still the standard surgical treatment of renal tuberculosis when the other kidney is free from infection or only slightly infected. This measure is based on the sound principle that a resistant tuberculous focus is best removed when this is anatomically and physiologically feasible. At a conservative estimate nephrectomy more than doubles the chance of cure; and the antibiotics have not much altered this, for although they have improved the results of non-surgical treatment they have also greatly improved the results of nephrectomy, particularly by promoting smooth healing after operation. Nevertheless the limitations and disadvantages of nephrectomy are obvious. The operation is at the same time too radical and not radical enough: it is too radical if the kidney contains healthy tissue, as is very commonly the case; and it is not radical enough because it leaves untouched the original extra-urinary focus, and possibly also small foci of disease in the other kidney. On these grounds there is a clear prima-facie case for partial nephrectomy; and SEMB,[4] in an account of 87 cases treated by this method, shows that this is both feasible and successful. SEMB compares renal with pulmonary tuberculosis in regard to pathological anatomy and surgical treatment. In both conditions small parenchymatous foci may heal, especially with the help of antibiotics; but cavities (the ulcerocavernous or caseocavernous lesions of renal disease) are much less likely to heal, especially in the kidney. Twenty years ago the surgical treatment of a solitary cavity in the lung which resisted lesser measures might have been total thoracoplasty; nowadays it would probably be segmental resection. A solitary caseocavernous lesion of a kidney is still usually treated by total nephrectomy; and SEMB considers this unjustifiable. The results of partial nephrectomy in his hands are, from the point of view of cure, at least as good as those of total nephrectomy. There is one reservation: none of his cases has yet been followed for more than five years, but even so the results are excellent. There have been no deaths, and the general condition of all the patients is satisfactory; in nearly 90% the urine remains free from evidence of tuberculous infection. In only 2 cases did the function of the partially resected kidney fail; and the series includes 13 cases in which part of the only remaining kidney was removed. These results at least justify a thorough trial of this method.

Partial nephrectomy is not a new operation. It was first performed as long ago as 1887 by CZERNY (for tumour), but until recently it was only rarely done. In 1937 GOLDSTEIN and ABESHOUSE[5] collected a series of 290 reported cases and described 6 of their own. Only 41 of these operations were for tuberculosis, and the results were poor; of the 41 patients, 5 died, 5 developed a urinary fistula, and 6 required a secondary nephrectomy. The operation was much more often and more successfully done for stone; and hitherto it has been practised mainly for this disorder. Of 155

Whitestaunton	21	22	16	31½	—
School total	1436	1094	591	1266	9
Other notifications			7	10	3

Some children affected did not take school milk This is explained in two ways

(1) On Sept 24 the schools receiving midday meals from the central school kitchen had rice pudding Although this was made from satisfactory milk it was stodgy, and in some cases the school milk was used to make it more palatable

(2) Some children who did not drink the school milk came from homes supplied from the same source They were infected in common with other members of their family

The adults were affected in one of these two ways

No obvious difference in susceptibility was noticed, and there was no sex difference The fact that fewer older children were ill is explained by the fact that, whereas the percentage of milk drinkers is about 90 among young children, it is only about 50 in older children The small number of adults is explained by the fact that few went to the doctors for treatment, and therefore the exact number is unknown Less milk was distributed to the public than to the schools No doubt also most adults take their milk in some hot beverage, such as tea, and the bacterium is often destroyed in this heating

BACTERIOLOGY

All of the 7 specimens of fæces obtained from persons with symptoms of food-poisoning contained *S dublin* The Salmonella Reference Laboratory confirmed the identification

S dublin having been isolated from Ladybird's milk, it was important to discover how she had become infected She had calved four or five days before becoming ill, and her calf had been put on the herd nursing cow First, the farm hands were examined, and samples of their fæces were sent to the laboratory, all were negative It was discovered that one of the milkers (A B), who was on holiday during the week of the outbreak, had been infected in a smaller outbreak due to the same organism on an adjacent farm in 1947 He had assisted at Ladybird's calving, and this was regarded as highly suspicious However, repeated specimens of his fæces proved negative The report on his blood was as follows

S typhi	(O)	1/80 + 1/160 trace
S paratyphi B	(O)	Less than 1/40
S paratyphi B	(H)	
S enteritidis	(H)	1/40 " "

S dublin shares the (O) antigen of *S typhi* and the greater part of the (H) antigen of *S enteritidis* The paratyphoid antigens were used as controls The results suggested an old rather than a recent infection in agreement with his history His medical practitioner states from his records that A B had had pyrexia of unknown origin in September, 1950, and had been off work for thirteen days, he then had headache and abdominal pain and was treated with penicillin He did not respond, but his temperature subsided slowly, after being about 100°F for five days Infected persons have been known to carry *S dublin* for twenty one months (Harhoff 1941), but nobody for five years In spite of the rarity of carriers of salmonella and the negative findings, A B must remain under suspicion

As the milk from an adjacent farm had been the cause of a smaller outbreak due to the same organism in 1947, it was considered that there might be a link between the two farms, possibly a common contaminated water-supply Moore swabs (Moore 1948) were inserted in the water supplies to both farms, and in all streams and drains nearby None of the swabs were positive

As Ladybird's fæces were positive, it was suggested that the milk had been contaminated in handling She was slaughtered, and her udder was removed and opened aseptically, samples of milk were pipetted off from each quarter, and *S dublin* was recovered from the milk Her liver was enlarged and pale and showed signs of fatty degeneration, but it was not sent to the laboratory Clarenburg and Vink (1947) have found that, when other organs are affected the liver always contains *S dublin*

The remainder of the herd were examined by the regional veterinary investigation centre of the Ministry of Agriculture and Fisheries None of the samples of milk and fæces contained salmonella No samples of blood were taken Ladybird's calf, which had been on the mother for only two days before she became clinically ill was found to have *S dublin* in the fæces, it did not infect the nursing cow on whom it was put, and recovered after treament with sulphadimidine On Oct 2 a heifer developed symptoms of enteritis, it did not respond to treatment, and was slaughtered on Oct 9 A cow was similarly affected on Oct 11, and slaughtered on Oct 14 On Nov 5 a further cow was affected and was given treatment, she appeared to be healthy, but on Nov 24 still had *S dublin* in the fæces She has not been allowed to return to the herd It may be of significance that all the animals infected appeared to acquire the disease in a field which is used annually for the local agricultural show The possibility of infection persisting at the site of the latrines was considered, but a few bacteriological examinations of the soil were unproductive Another feature of this field may be of more importance alone of all those in use on this farm it depends for drinking water on a brook, the river Isle at Eleighwater, which rises some two miles away, near the farm which was the source of a small milkborne epidemic in 1947 Field (1948) has shown in West Wales that *S dublin* infection of cattle is not uncommonly waterborne

CARRIERS

In a boys' school, where 29 of the boarders were affected, samples of fæces were taken from them all on Sept 29 They were all negative

It was expected that secondary cases would follow due to healthy carriers In an effort to detect these carriers Moore swabs were inserted in the main drains of all the schools before they entered the sewers or soakaway four weeks after the outbreak Not one of these was positive

The only person known to be still unfit at the end of November was a kitchen hand Although specimens of her fæces were negative, she was still having abdominal discomfort and occasional severe diarrhœa She finally returned to work symptom-free on Dec 1, when her stools were still free from *S dublin* partial nephrectomies reviewed by Hanley[6] in 1950, 125 were for stone and only 8 for tuberculosis. Many patients in this series were operated on before the advent of streptomycin; this antibiotic has widely extended the field of partial nephrectomy, especially for tuberculosis because of its effectiveness against tuberculous infection of the wound. In total nephrectomy for tuberculosis the minimal requirements are that one kidney is tuberculous and that the other is free from infection and functioning adequately. For partial nephrectomy, more precise information is essential. The details of renal anatomy are of prime importance—particularly the arrangement of the calyces, with its variations, and the blood-supply. Semb adopts Fölgren's scheme, according to which the kidney has seven pairs of pyramids, dorsal and ventral. These pairs are grouped into three divisions; the uppermost three pairs constitute the upper division, and the remaining four pairs are divided equally between the intermediate and lower divisions. In addition to this, there are six different ways in which the pelvis may branch to make the calyces of the middle division. The ramification of the renal artery and vein varies considerably, especially outside the kidney. Semb's scheme of pathological anatomy divides tuberculous renal disease into three groups.

In the *first group* there are small tubercles or tuberculous infiltrations which may lead to the excretion of tubercle bacilli in the urine, but in which there is no macroscopic destruction and especially no open communication with pelvis or calyx. This he calls the "parenchymatous" group, and it is not a surgical problem. For one thing this type of lesion may now often be cured by medical treatment; and for another it does not lend itself to pyelographic study, so that a detailed anatomical diagnosis cannot be made.

The *third group* he terms the "total destructive," in that all three divisions of the kidney are macroscopically affected and often the ureter is also involved. Obviously partial nephrectomy has no place here.

The *second group*, termed "local-destructive," is the group for partial nephrectomy. Here the macroscopic destruction may involve as little as one part of one pyramid or as much as two complete divisions of the kidney.

This second group constitutes no less than 56% of all cases of renal tuberculosis in Semb's series—which shows how important a part may be played by partial nephrectomy.

By Semb's scheme, which he describes as selective medical-surgical treatment, the patient always undergoes preliminary sanatorium treatment, which may last as long as six months if there are other active foci or the general condition is poor. Antibiotics are used sparingly in this phase, streptomycin being restricted to a total amount of 15 g. In the postoperative phase a rather larger amount is allowed—up to 40 g. in uncomplicated cases. If operation on extra-urinary lesions is necessary, this is done before the operation on the kidney. The renal lesions are accurately charted by means of excretion and instrumental pyelography. Aortography is also much used; Weyde,[7] the radiologist associated with Semb, has described the technique and results. He emphasises the importance of the "nephrographic" effect, which maps out the areas of non-functioning parenchyma, in addition to the more obvious effect which delineates the individual vessels.

Ample exposure is necessary for partial nephrectomy, and Semb favours access through the bed of the eleventh or twelfth rib.

A bloodless field may be obtained either by clamping the pedicle or by compressing the renal substance; but Semb found when operating on cases with a sole remaining kidney that the renal function took a harder knock when the pedicle itself was clamped. In his series the extent of the resection varied greatly from case to case, and in 95% of cases the lesion or lesions were removed in one block of tissue; the upper division was involved more than twice as often as the lower. The pelvis or neck of the calyx is sutured (in contrast to Stewart's[8] advice when operating for stone); and the vessels are dealt with mainly by ligature in the cut surface of the kidney, and more rarely by securing individual vessels in the hilum. The cut surfaces are sutured with a double row of catgut, the outer row getting a hold on the capsule; no fat or muscle appears to be used as a further safeguard against hæmorrhage.

Postoperative complications have been remarkably few, consisting in wound infection (3 cases) and failure of function of the remaining tissue (2 cases); there has been no urinary fistula and no postoperative hæmorrhage.

These good results show that in the immediate postoperative phase partial nephrectomy can be no less safe and satisfactory than total nephrectomy. It is reasonable to expect that the late results will also be good, in view of the excellent showing at five years; for we know that after total nephrectomy 75% of the deaths occur within five years. The least that can be said is that here is a method of surgical treatment which is based on sound principles, conserves functioning tissue, and gives promise of improved results.

Annotations

COMFORTABLE CHILDBIRTH

The Government's campaign to ensure that every midwife shall know how to give gas-and-air analgesia for the relief of pain in childbirth has eventually been very successful. By the end of 1951, 94% of all midwives in England and Wales had been trained in the use of the method; and the National Birthday Trust Fund, as Mr. William Penman, the acting chairman, points out,[9] have done much to ensure that enough machines be available. He has analysed the official figures of domiciliary confinements attended by midwives in 1951, to show how many of the mothers received gas-and-air analgesia. The results show a wide variety of practice throughout the country.

There were 253,069 domiciliary confinements attended by midwives during the year; in 192,529 of them the midwife acted as midwife, and in 60,540 as maternity nurse. Analgesia was given in 60% of the first of these two groups and 51% of the second. Of the 146 administrative units in the country, 1 reported that confinements in which analgesia was given amounted to only 8% of the total, and in another 2 the figure was only 16%. At the other end of the scale, 15 units reported figures of 80–90%, and 5 others over 90%. The mean for the country as a whole was 58%.

Clearly it is one thing to train a midwife in the use of this method, and another to get her to use it. From the wide variation in the figures up and down the country it seems that she may be influenced by something more than the views of the mother—perhaps by the views of the medical officer of health. It would be convenient to know just how often relief in childbirth is really needed: medicine sorely lacks a handy little machine

EFFECT ON SCHOOLS

The most serious effects of the outbreak were felt by the school population, the work of the smaller schools being completely disrupted The loss of 1256 school days in a term due to one outbreak is considerable If children work a five-day week for forty weeks a year, this is equivalent to more than six years In an epidemic of this size it would probably have been necessary to close the schools , but a weekend intervened, and by the following Monday the number of absentees was many fewer than when they had closed on the Friday

PASTEURISATION

The opponents of pasteurisation always use as one of their strongest arguments that children will never drink "cooked milk" Of course, if there is a cooked taste about pasteurised milk the technique is at fault, and usually it is impossible for a normal person to detect whether milk is raw or pasteurised

This outbreak occurred in a rural area and one of the most important milk-producing areas in the country Most of the children came from villages and probably have as sensitive a palate as any, so far as milk is concerned It is therefore interesting to see what effect the outbreak had on the school consumption of milk

Before the outbreak 1094 of 1436 children were taking milk in the affected schools Three months later 1030 of 1443 were taking milk The weather then was considerably colder, and there is a slight seasonal falling off in the consumption of milk every year Immediately after the outbreak there was a considerable drop in the numbers However, they have slowly increased, and now are 64 less than previously The fall in numbers has been greatest in the rural primary schools and the private girls' school There has not been one complaint by the children against the heat-treated milk The fall is entirely due to parents stating that they do not wish their children to take the milk It was noted in this part of the investigation that the number of children taking milk in schools depends a great deal on the head teacher, particularly in the smaller schools

DISCUSSION

In many previous outbreaks the milk has contained *S dublin* owing to fæcal contamination, yet efforts to isolate it from the milk failed (Conybeare and Thornton 1938) No record has been found of any outbreak in which so many persons have been affected Tulloch (1939) reported that, in 1926, 373 persons were affected by a milk-borne outbreak due to *S dublin* in Dundee The large number in the present outbreak may have been due to the fact that in this instance the cow was excreting *S dublin* in considerable numbers and the milk was more heavily contaminated than might otherwise have been the case The morning milk, which was the contaminated milk and was later bulked with the afternoon milking, was not refrigerated till evening, and in the meantime incubation could easily have taken place

The original source of infection is still undiscovered The fact that one milker was involved in two outbreaks in five years is interesting, but it must be remembered that *S dublin* is the commonest found in bovines (Ritchie and Clayton 1951) However, if he were the cause, which has not been proved, he might well have infected the cow during calving She was originally presented as a case of mastitis and only later developed bowel symptoms

CONCLUSIONS

Notification —This was a large outbreak which the health department was able to notify to the general practitioners It would therefore be reasonable to expect 100% notification of cases treated , but this was far from being achieved One is bound to assume that a large number of small outbreaks must occur which go unnotified or may be notified much too late for any useful investigation to be made The health department was fortunate in this instance that the acting head teacher of a school reported to it immediately by telephone The investigation could thus be brought to a satisfactory conclusion very much sooner than might otherwise have been possible

School Milk and Meals —In this area the medical officer of health is also the medical officer responsible for inspections in the schools The source of the school food and milk was therefore known to him without investigation, and this again was an important factor in avoiding waste of time

T T Milk —The source of infection in this outbreak was T T raw milk The fact that the milk supply is tuberculin tested leads to a false sense of security, as this outbreak has shown

RECOMMENDATIONS

General practitioners should be asked to inform the health department whenever two or more similar cases of food-poisoning occur simultaneously, because only a small percentage of patients seek medical advice The health department can then get in touch with other general practitioners, who may have like cases

Where the medical officer of health is not the school medical officer it is a great advantage for him to be informed of the sources of milk and meals at all schools in his area as a routine

Wherever possible, pasteurised milk should be supplied to schools, even if extra expense is incurred in so doing

SUMMARY

An explosive outbreak of food-poisoning due to *Salmonella dublin* affecting 610 known cases in Somerset in 1952 is described The food causing the outbreak was T T raw milk supplied to schools and the public

S dublin was isolated from the milk, udder, and fæces of the affected cow It was also recovered from all samples of fæces from patients showing signs of illness

When pasteurised milk was supplied the epidemic finished in a few days

My thanks are due to Dr J A Boycott, director of the Public Health Laboratory, Taunton, for laboratory work, for help and advice throughout the investigation, and for criticism of this report , to Mr W B Martin, M R C V S , for help in the investigation of the herd , to the sanitary inspectors of the Chard Rural District Council, especially Mr Eric Whisker, whose help was invaluable, particularly in the early stages of the inquiry , and to Mr J Handel, acting headmaster, whose prompt action in telephoning the health department had such an important bearing on the investigation

Food-poisoning in Lancashire

The Minister of Health, answering a question in the House of Commons on June 18, said that 734 cases of food-poisoning had been notified in Preston and the surrounding district up to June 17 15 patients were still in hospital, and there had been 1 death The source of infection was meat pies, contaminated with a virulent form of salmonella The manufacture of these pies had been stopped, and investigations were continuing to determine the way in which they had become infected He was satisfied that all appropriate measures had been taken to control the outbreak, which now appeared to be at an end

Dr A Dodd, medical officer of no 3 division of the Lancashire county area, tells us that the food responsible was approximately 6000 meat pies manufactured in to measure and compare the interpretation of pain by different subjects. Childbirth presents peculiar difficulties. As Mr. Penman himself points out, we know that in a proportion of cases women either do not need, may not have, or refuse to accept analgesia; but he thinks this proportion is a small one. The average of 58% of administrations of analgesia is, he thinks, "much too low"; and it is very hard indeed to know whether he is right. Those experienced in training mothers to relax, in preparation for confinement, say that it is often possible to ensure a painless labour without analgesia. Many hospitals and antenatal clinics nowadays arrange classes in which mothers learn to exercise the voluntary muscles concerned in labour, as well as how to relax; and are also taught a little about their own physiology. We have lately mentioned the scheme of this kind run by Prof. W. C. W. Nixon's team at University College Hospital.[10] The Maternity Centre Association of New York holds an elaborate course, which includes not only exercises but also lectures, attended by both mothers and fathers, on the anatomy and physiology of reproduction. They have published a set of clear illustrations of the exercises, which are based on those of the late Helen Heardman.[11] The lecture course ends with a "labour rehearsal," in which the whole birth process is reviewed, and the parents are given the chance to ask plenty of questions. Thus prepared for the birth, mothers feel little fear, and avoid much of the pain associated with anxiety and tension.

It would be unfortunate if our concern over the pangs of labour diverted our attention from the mother as a whole. The Family Planning Association, in a sensible pamphlet,[12] put the picture in proportion. Anæsthesia or analgesia, they say, can render even the most difficult labour nearly painless, and the mother will wake to find her baby comfortably born. But, they add, it must not be forgotten that many women find childbirth an exhilarating experience, which, though hard work, is not attended by pain; and the question arises whether "this taking of the birth-process out of the mother's control produces in her the same feeling of accomplishment as when she has consciously coöperated in the birth of her child." The Birthday Trust Fund wish to see enough gas-and-air analgesia machines available, and enough midwives trained in their use, for every mother who asks for it to have relief in childbirth. It is not possible, without further research, to say what proportion do ask for it at present, still less how many need it, or whether fewer would need it if more were prepared for childbirth on the lines followed at University College Hospital. A rate of 8% of administrations is almost certainly unkindly low; but a rate of over 90% may be equally unkindly high. Training in relaxation takes time and trouble; analgesia is in some sense a short cut. If our aim is to do the best we can for the mother we must take all her needs into account, neither exposing her to wasteful needless pain, nor deposing her too officiously from control of her great occasion.

VEGETABLE JUICES

JUICES obtained by pressing vegetables in special apparatus have attracted little interest in Britain. They have been popular, however, in America as beverages or cocktails, and in German-speaking Continental countries as therapeutic agents. Dr. H. E. Magee,[13] of the Ministry of Health, has studied the evidence favouring the use of juices for either of these purposes. With the coöperation of Mr. Russell Allen, PH.D., he has also collected further information on the chemical composition and nutritional value of juices pressed from many common vegetables, including broccoli leaves, cabbage, carrots, celery, kale, melon, parsley, spinach, tomato, and watercress.

All the juices examined contained sugars, but in widely divergent amounts. Thus carrot juice contained 7·11%, estimated as glucose, in contrast to only 0·2% in the juice of watercress. Equally large variations were found for minerals. Thus iron averaged 2·12 mg. per 100 ml. in watercress and 0·08 mg. in tomato; calcium averaged 18·7 mg. in broccoli leaves and only 0·75 mg. in spinach. Vitamin B_1 was richest in cabbage juice, but this vitamin was completely absent from spinach juice. These divergencies may be traced partly to corresponding variations in the unpressed vegetables, for which Magee quotes official data, and partly to variations in the efficiency with which the nutrients are passed into the juice. Probably the low calcium contents of spinach juice may be related to the high concentration of oxalic acid in this vegetable, which may immobilise calcium in the form of its insoluble oxalate. On this idea it is difficult to explain, however, either why iron should be included fairly freely in the juice or why vitamin B_1 should be excluded. Too much faith, of course, cannot be placed in comparisons on sets of data which were obtained on the juice and unpressed vegetables on different occasions. Thus in order to reconcile the value of 3% found for sugar in broccoli juice with the value of 0·4% quoted for the unpressed vegetable we must suppose an efficiency of extraction which appears almost impossible. From 100 g. of leaves not more than 13 ml. of juice would have to be pressed, and this small volume of fluid would have to carry the entire sugar contents of the original material.

The antiscorbutic power of fresh vegetables is one of their most important nutritional virtues, and vitamin C might be expected to appear in the juice in company with other water-soluble substances. It is well known, however, that when plant cells are damaged they liberate enzymes which destroy the vitamin. High pressure would obviously rupture the cells and the juices would be expected to have antiscorbutic activity only if consumed very promptly, or if effective steps were taken to stabilise the vitamin. Since many of Allen's analyses for ascorbic acid were made several days after the expression of the juice it is not surprising that most specimens were quite inactive. A striking observation, however, was made on kale juice, which had retained no less than 46 mg. of ascorbic acid per 100 ml. By contrast, a specimen of cabbage juice, freshly prepared by Mr. V. L. S. Charley, contained only 8·5 mg. per 100 ml. Magee suggests that either kale does not contain ascorbic acid oxidase, or an anti-enzyme is present. Further attention to this interesting point seems highly desirable. Substantial amounts of carotene were found only in juices from carrots and watercress.

Reports that vegetable juices are effective in the treatment of obesity and allied conditions, such as hypertension, disease of the gall-bladder, and cardiovascular disturbances are explained by Magee on the assumption that dosing with juice is usually accompanied by a strict curtailment of the food intake. He attributes the benefits ascribed to vegetable-juice therapy in rheumatic conditions to their general nutritive value, although it is difficult to see what advantages they would have over the unpressed vegetables. He seems prepared to accept the strong claims of Cheyney[14] and others that large doses of juice, particularly from the cabbage, are effective in the treatment of gastro-intestinal disorders. Presumably the pectin present in raw juices absorbs toxic substances and bacteria from the bowel.

a large bakery on June 10 and 11 Possibly too some pies baked on June 9 and 12 were infected

A report on the morning of June 13 of 2 cases, and the information that meat pies, among other foods, had been eaten, resulted in a decision the same morning to stop production of meat pies Staff concerned were interviewed and excluded from work when this was justified, and fæcal specimens were submitted for investigation Steps were taken to get unsold meat pies destroyed or subjected to laboratory tests

Salmonella bovis-morbificans was isolated from fæces of patients affected and from the meat pies but not from the constituents (it has not been possible to obtain samples of meat from each source) Salmonella organisms were isolated from several persons employed at the bakery who were probably infected by eating meat pies, but the findings in one case may prove significant Investigations continue, particularly concerning meat-supplies

Clinically the incubation period has varied from 6 hours up to 30 hours—18 to 24 hours has been common Shivering and colic or vomiting (sometimes very prominent) has been followed by diarrhœa accompanied by headaches, pains in the limbs and general prostration The illness has lasted for from 8 hours to 5 days The severity of symptoms has been very variable Primary cases are still being reported, and also a few secondary cases

Up to last Monday the outbreak was thought to have involved over a thousand cases[1], and a death in Lancaster on June 20 may have been due to the infection[2]

Lining a Reservoir

A rubber bag holding 12 000 000 gallons of water is to be fitted into a reservoir at Easington near Sunderland, which was cracking because of coal workings After two years' experiments and tests Sunderland and South Shields Water Company have accepted the Dunlop Rubber Company's plan for fixing 16 000 square yards of rubber to the reservoir with a ton of adhesive The rubber bag will weigh 100 tons

Parliament

QUESTION TIME

Negligence in a Military Hospital

Wing Commander N J HULBERT asked the Secretary of State for War whether inquiries were now completed in regard to the death of Private Donald Harrison, of Stockport, who died in Moston Hall Military Hospital in April —Mr A H HEAD replied Private Harrison, a young man aged 18, was called up for military service in January, 1953, when he was passed as medically fit On March 13 at Wrexham he reported sick with a pain in his back which the medical officer in charge of his unit diagnosed as fibrositis He again reported sick on March 26 when the medical officer diagnosed "Query hysteria" and ordered his admission on March 26 to the military hospital at Chester

On admission he was given, by the admitting medical officer, a preliminary medical examination which included a detailed examination of the central nervous system for the purpose of allotting him to the appropriate medical division of the hospital The admitting officer made a firm but not final diagnosis of hysteria This preliminary examination was correct in so far as Harrison was undoubtedly suffering from hysteria The fact that it was not discovered that he was also suffering from a rare and malignant disease was not necessarily at this stage due to negligence since a more detailed subsequent examination should have taken place after admission to the ward

After admission Private Harrison was required by the medical staff of the hospital to fend for himself and other patients were forbidden to help him The treatment of hysterical patients does require that they should be encouraged to help themselves but in no circumstances should it entail harshness Although he complained that he could not use his legs he was left to get about as best he could by himself This treatment continued for five days during which time Harrison's condition deteriorated, and I am satisfied that the continuance of this type of treatment was due to negligence and undoubtedly resulted in harshness A full physical examination is always required before a diagnosis of hysteria can be justified and should have been made on the first day in the ward The medical specialist looking after Harrison should have satisfied himself that this had been done This he neglected to do Furthermore although during these five days Harrison frequently complained of pain in his legs thighs and back, and although this was recorded by the subordinate nursing staff, the day sister in charge of the ward never drew the attention of the medical specialist to Harrison's repeated complaints

This wrong and harsh treatment was continued despite the comments and protests of at least one other patient in the ward It was not until March 31 that Harrison was seen by a psychiatrist and thereafter received sympathetic handling but even at this stage a full examination had not been made On the night of April 1 the medical orderly became worried about Harrison's condition and called the orderly medical officer and then for the first time Harrison was given a full medical examination The orderly medical officer realised at once that Harrison was dangerously ill, and from this time he was treated for the malignant disease from which he was suffering Harrison died early on the morning of April 5 At the time of his admission to hospital Harrison's illness had undoubtedly reached a stage when death was inevitable since malignant disease of this type in youth, though rare, grows very rapidly I do not suggest that this in any way excuses the mistakes made in the handling of this case

After Harrison's death it should have been abundantly clear to the commanding officer of the hospital that serious irregularities and mistakes had occurred Yet as far as I can ascertain, no thorough inquiry was instituted by the commanding officer although on May 18 he stated that a full inquiry had already been made by himself and that he was satisfied that there was no truth in the allegations that there had been ill treatment of patients

I have been into the whole of this serious occurrence most carefully and I am convinced that it was caused not by any fault in the method of procedure laid down for Army hospitals but by the failure of certain individuals to carry out their duties Members of the Army Medical Services carry heavy responsibilities and those who fail to discharge them must be called to account The commanding officer will be called to account for his conduct in this matter and is to be tried by court martial The medical specialist concerned, who left the R A M C in May, will be reported to the General Medical Council The day sister concerned, who is a civilian, has had her contract terminated and will be reported to the General Nursing Council

I have written to the mother of Private Harrison expressing my extreme concern and disquiet about the way her son was treated, and I would like also to tell the House how much I regret this lamentable occurrence

N H S Specialists in Scotland

In answer to questions as to how many specialists were employed under the N H S in Scotland Commander T G D GALBRAITH gave the following figures

Date	Consultants			S H M O s			Total Consultants and S H M O s		
	Whole time	Part-time	Total	Whole time	Part time	Total	Whole time	Part time	Total
31 12 49	283 (43 8%)	363 (56 2%)	646	163 (59 5%)	111 (41 5%)	274	446 (48 5%)	474 (51 5%)	920
31 12 50	325 (45 9%)	383 (54 1%)	708	174 (59 8%)	117 (40 2%)	291	499 (49 9%)	500 (50 1%)	999
31 12 51	348 (47 6%)	383 (52 4%)	731	205 (63 9%)	116 (36 1%)	321	553 (52 6%)	499 (47 4%)	1052
31 12 52	372 (49 6%)	378 (50 4%)	750	219 (66 4%)	111 (33 6%)	330	591 (54 7%)	489 (45 3%)	1080
31 3 53	368 (49 2%)	380 (50 8%)	748	224 (67 3%)	109 (32 7%)	333	592 (54 8%)	489 (45 4%)	1081

In his own experiments he has proved the high buffering power of vegetable juices against acids. Spinach extracts are superior to milk in their buffering power, and would therefore be expected, for theoretical no less than for practical reasons, to be valuable in the treatment of gastric hyperacidity.

Despite these virtues Magee sees little future for the consumption of vegetable juices by healthy persons. Even the best pressed juices, unlike purées, contain only small fractions of the nutrients present in the original vegetable. The residue after pressing, moreover, contains not only assimilable nutrients but roughage which assists peristalsis. There seems to be no scope in this country for the more extensive use of vegetable juices, except as components of invalid diets and as occasional cocktails.

CHEMOTHERAPY OF ACTINOMYCOSIS

BEFORE the introduction of sulphonamide therapy actinomycosis caused by the anaerobic *Actinomyces israeli* was treated principally with potassium iodide; and even now, probably because of its effect on the granulomatous infiltration, this is sometimes a useful adjunct to the antibiotics.

Early results with the sulphonamides in the treatment of actinomycosis seemed very successful; but apparent cure was sometimes followed by relapse, and even long courses of carefully controlled treatment were often unsuccessful. The application of antibiotic therapy was attended by many dramatic cures, even in very severe cases; and soon penicillin eclipsed the sulphonamides. Continued use of penicillin, however, brought a crop of failures. Many of these were due to inadequate initial dosage with which the infecting micro-organism became resistant. This danger was largely averted by giving massive doses in the initial stages. Garrod[1] showed by in-vitro tests that each of the five antibiotics in common use—penicillin, streptomycin, aureomycin, chloramphenicol, and oxytetracycline (terramycin)—are bacteriostatic to strains of *A. israeli*. Streptomycin, aureomycin, and chloramphenicol have been administered chiefly in cases where penicillin had already failed; and often one of these three has effected a remarkable cure. This does not imply, however, that any of the three is always superior to penicillin: the antibiotic that is the most effective in one case may be the least effective in another. Kelly[2] described a case of abdominal actinomycosis in which, after unsuccessful treatment with penicillin in large doses, sulphadiazine, and streptomycin, clinical improvement was obtained with chloramphenicol; but relapse ensued, and eventually cure was rapidly effected by administration of aureomycin. In another case, reported by Torrens and Wood,[3] streptomycin arrested the disease after penicillin, the sulphonamides, iodides, and surgical measures had failed.

It seems possible that the infecting strains of *A. israeli* may differ in their sensitivity to particular antibiotics; but a preliminary sensitivity test of the culture against the individual antibiotics should enable the most suitable to be chosen. So far the newer antibiotics have had only a very limited trial in the initial treatment of actinomycosis; so a fair comparison with penicillin is not feasible. The first important therapeutic trial of oxytetracycline in actinomycosis is reported by Lane et al.[4] who successfully treated with it 7 cases of the oro-cervico-facial type of the disease. The disease, which was of dental origin and in some cases followed extraction of teeth, was in the lower jaw and was related to the molars and bicuspids; it was localised and acute; its average duration before the start of treatment with oxytetracycline was only five and a half weeks. Suppuration occurred in all cases, and *A. israeli* was isolated in culture from the pus. In 6 of the patients the disease was rapidly cured by oxytetracycline in doses of 500 mg. by mouth every six hours for adults, with proportionately smaller doses for children; treatment was continued for from two to six weeks. Of these 6 cases, 3 had previously been treated unsuccessfully with penicillin, and 1 had become penicillin-resistant. The 7th case was treated at first with penicillin and chloramphenicol and responded well to the latter; but an urticarial rash appeared and the treatment was stopped. Six weeks later, oxytetracycline was given in doses of 250 mg. every six hours for eight days, and this short course of treatment brought about apparent clinical cure. The disease recurred eight weeks later, but it responded well to a further course of oxytetracycline in doses of 500 mg. every six hours, supplemented by small doses of potassium iodide.

Another group of drugs has proved useful in treating actinomycosis. Schoenbach et al.[5] reported encouraging results from the treatment of 3 cases of blastomycosis (*Blastomyces dermatitidis*) with stilbamidine intravenously and propamidine applied locally to the lesions. A diet low in protein and purin is advisable during this treatment. Miller et al.[6] treated a case of actinomycosis of the jaw with stilbamidine injected intravenously at rather longer than daily intervals, starting with 0·05 g., which was increased rapidly to 0·15 g., in 200 ml. of 5% glucose solution. The first course lasted three weeks; and, after an interval of sixteen days, a second course was given over a period of two weeks, which resulted in apparently complete clinical recovery. This patient had previously been treated unsuccessfully with procaine penicillin and sulphonamides. Another agent, pregnenolone acetate, was used with success by Lamb et al.[7] in treating a local infection by an acid-fast actinomycete (*Nocardia* sp.) in a girl aged 6. No indication of toxicity or metabolic disturbance was found after a total dosage of 60 g. given over a period of eight months.

COLONIAL HEALTH SERVICES

IN the Colonial territories increasing population, urban concentration, improved transport, and ever more lively awareness of the benefits of Western medicine are straining the medical services, especially in the main centres. Thus in Singapore the annual hospital outpatient attendance, which averaged 90,000 immediately before the late war, is now approaching 600,000; and in some maternity wards deliveries number about 90 per bed per annum. As regards medical staff, a high rate of recruitment from the United Kingdom and other Commonwealth countries was achieved in 1951; and the latest Colonial Office report[8] records that this rate was maintained in 1952, when 147 doctors were appointed (18 for West Africa, 42 for East and Central Africa, 47 for South-east Asia, 24 for the West Indies, 9 for the Pacific area, and 7 for other territories). In addition medical officers of local origin are steadily increasing, particularly in the Far East, West Africa, the West Indies, Cyprus, and Mauritius; and at the end of January this year 638 Colonial students were studying medicine in the United Kingdom or Eire. The number of specialist posts has been increased; it has proved impossible to fill all such posts from within the service, and, notably in the fields of radiology, anæsthetics,

Tuberculosis in Glasgow

Mr **John Rankin** asked the Minister the number of new cases of pulmonary tuberculosis notified in Glasgow in the first quarter of 1953, and how this compared with each quarter of 1952 and 1951 —Commander **Galbraith** replied There were 622 notifications of pulmonary tuberculosis in the first quarter of 1953, a higher figure than in any of the quarters in 1951 or 1952 except the 644 in the second quarter of 1951

Mr **Rankin** asked the Minister how many beds were available, per 100 new notifications, for the treatment of pulmonary tuberculosis in the whole of Scotland and in the area under the Western Regional Hospital Board —Commander **Galbraith** replied At the end of 1952, the ratio was about 82 beds per 100 notifications for Scotland as a whole, and about 77 beds per 100 notifications for the Western Region alone

Nurses and Pencillin Sensitivity

Mr **Alfred Hargreaves** asked the Minister of Health the number of district nurses who had developed a sensitivity to penicillin and could not undertake further nursing duties, and what special precautions were available to protect nurses exposed to this risk —Mr **Iain Macleod** replied The total number of district nurses affected is not known, but a special inquiry has shown that in 70 local health authority areas 73 nurses had become sensitive to penicillin, and had to give up nursing for varying periods There is evidence that the incidence can be reduced by strict observance of technical precautions and I have at once obtained advice on this from my Standing Medical Advisory Committee I am circulating this advice urgently to local health authorities and others concerned Nurses who have to give up work by reason of sensitivity to antibiotics are entitled to the normal sick leave allowances and may, in appropriate cases, qualify for incapacity benefit under the National Health Service (Superannuation) Regulations They may also, when the circumstances warrant it, qualify for industrial injuries benefit The numbers, if any, who may have to give up nursing permanently are not yet known

Mr **Hargreaves** Would the Minister consider approaching the employing authorities so that they may gain the requisite information from their nursing superintendents? Would he compare the means whereby penicillin is administered in hospitals where the incidence of this sensitivity is less, and possibly learn of a method by which this risk can be reduced for nurses who have to undertake the administering of a great deal of penicillin? Mr **Macleod** I will look carefully into what the hon Member says I know there is a great deal of truth in it Perhaps I might send him a copy of the advice I have been given by the Medical Advisory Committee, which covers many of the points he raises

Chalk Content of Flour

Dr **Barnett Stross** asked the Minister of Food the total amount of chalk added to flour in any given year, and from what source the chalk was obtained —Major **Gwilym Lloyd George** replied In the twelve months ended May 23, 1953, 11,369 tons of calcium carbonate were added to National flour The whole of the supplies conformed to the specifications of the *British Pharmacopœia* and were obtained from home sources

Dr **Stross** Is the Minister aware that a great deal of discussion is going on whether there is any need to add chalk to our flour today, and that the original views are suspect? Are the Ministry of Food doing anything to check up on this problem and see whether the use of this substance can be discontinued?—Major **Lloyd George** The hon member knows that unanimity very seldom exists on these points This was the result of the Committee of 1941 The reason that it is still being maintained is because there is a proved deficiency of calcium intake in our diet Dr **Stross** Does not the Minister agree that recent experiments in South Africa have shown that the work in 1941 may well be not as accurate as we should like and may not justify the use of 11,000 tons of chalk in our flour every year? Will the Ministry of Food look at this question again? Major **Lloyd George** I am always prepared to look at important matters of this sort, but it is admitted that there is a very serious shortage of calcium intake

In England Now

A Running Commentary by Peripatetic Correspondents

One of my most cherished possessions, purchased regardless of cost—five shillings, to be exact including frame—from a cottager patient of mine is a later version of the German picture *The Broad and Narrow Way* originally designed by Mrs Charlotte Reihlen of Stuttgart in 1862 and painted for her by young Herr Schacher of that city

Not much happens along the narrow way, which may be why it is attracting all too little custom There is a chapel, a Sunday School, a deaconess institute you may have a drink of water if you like and there is a loose lion to be negotiated, but after that it is all plain sailing or, rather, a short and gentle uphill stroll to a heaven of golden towers and minarets How different is the broad way Once through the inviting gate surmounted by "Welcome!" in large letters there is never a dull moment Small wonder that most people go this way, some of them by car and one of them on a bicycle Hardly are you inside before you are beckoned into a cottage by an attractive young woman If you prefer alcohol there is to your left a pleasant outdoor café, and within a stone's throw not only a theatre, but also a ballroom flying a union jack and open on Sundays

Beyond, with a loan office conveniently situated under the same roof is a gambling house, from an upstairs window of which is suspended the corpse of a (presumably unsuccessful) gambler On coming out of the loan office you may spend an amusing half-hour at the lottery table before going on past a couple of convicts to witness a pitched battle with a cavalry charge in progress backed by artillery and infantry (in that order) All the troops taking part are in full dress Just this side of hell there is a Sunday train, and dominating all is what is apparently an optician's sign Between heaven and hell there is a pretty solid looking rainbow

* * *

One of the many responsibilities of the present day householder is the execution of minor day-to day repairs A few weeks ago a disorder of function developed in an important piece of hydraulic machinery, and my own efforts at repair having resulted in the loss of what little remaining function there was, I was constrained to seek consultant advice from the local plumber He and his assistant soon restored the contraption to working order and in due course their bill was dropped through my letter-box

"Dr to Wm Bloggs & Bro
To taking down waste water preventor cistern, removing syphon box, making and fixing new copper clack, re assembling and refixing £1 1s

Reading this elegant document, my thoughts went back to those spacious days in the '30s when our paying patients provided us with both our bread-and butter and our motor-cars and when everything from the removal of a wen to an abdomino perineal resection was discreetly cloaked under the all-embracing term "For professional services" How much more satisfying for our patients, I thought, had they received bills after the style of my friend, Bill Bloggs

"Dr to Sir Probyng Lancet
To making 2 ft incision in abdominal wall, removing 5 ft of colon, joining lower end of small intestine to upper end of rectum and testing same for leaks, supplying, fixing and removing 24 mattress sutures 100 guineas

The only drawback would have been that our waiting-rooms would no longer have re-echoed to the tales of our past triumphs Instead our patients would have sat silently reading each other's bills

* * *

As part of our Coronation celebrations members of the staff planted trees in the hospital grounds It was a pretty expression of loyalty but I cannot help feeling that in their unanimous choice of ornamental cherries they missed a big opportunity for self-expression Would it not have been more appropriate, for instance, pathology, and psychiatry, it has even been difficult to recruit from the United Kingdom.

In most territories the full approved establishment has been reached or nearly reached; but this does not mean that needs are being fully met. As the report remarks, industrialisation, with its corollaries of migration of labour and the creation of new urban centres, has especially serious health implications in countries where tropical diseases are endemic and where local customs have not yet been fully adapted to the change from a predominantly rural economy. While the peoples of the various territories are turning with growing eagerness to the curative services, the trained personnel are growingly aware that in the long run their time might be more fruitfully spent on preventive action—and the report describes some striking instances of such action. A somewhat similar situation prevails in every country; but it is especially clear in the Colonies, where doctors are too few and there is great scope for prevention of endemic disorders. These two conflicting calls cannot be satisfactorily met without further expansion of the medical and allied services; and such expansion will depend chiefly on the recruitment and training of personnel from the territories concerned.

THE LISTER INSTITUTE

GOOD wine, it is said, needs no bush; and the governors of the Lister Institute do nothing to vaunt the distinguished work that proceeds under their ægis. Their latest report,[1] no less sober than its forerunners, records that during the past year Dr. A. A. Miles has taken up the directorship of the institute, and that Prof. W. T. J. Morgan, F.R.S., who heads the biochemistry department, has taken over the duties of deputy director.

Professor Morgan and Miss W. M. Watkins, PH.D., have been examining the reactivity of saline extract of certain plant seeds against human red cells of known phenotype, and have studied the inhibition of these reactions by preparation of the human blood-group substances and simple sugars of known constitution. It appears that L-fucose is of greater importance for H specificity than for A and B specificity, and that the N-acetylchondrosamine configuration may play an important part in A specificity. In another department Miss J. M. Horton, PH.D., has continued her work on the chemical fractionation of *Hæmophilus pertussis*, to extract the protective immunising antigen.

Polysaccharides extracted for formamide, alone or in conjunction with globulin, proved to be inactive although preliminary experiments had indicated some activity. The protective antigen, previously shown by F. L. G. Masry to be distinct from the hæmagglutinin and the toxin of *H. pertussis*, now appears to be distinct from the agglutinogen also. The protective action of rabbit antisera to the whole bacillus is unaffected by absorption with purified agglutinogen; and purified agglutinogen will not immunise mice actively. Alkaline extracts of *H. pertussis* yield a polypeptide antigen that appears to be antigenically pure agglutinogen. Variation in the potency of protective antisera with the route of administration of antiserum and infecting dose indicate that more than one type of antibody is concerned.

Dr. L. H. Collier, continuing his investigation of methods of preserving vaccinia virus, has found that purified virus freeze-dried in 5% peptone yields 100% succesful primary vaccinations after storage for four months at 37°C. Such a vaccine can be manufactured economically, and is shortly to be tested on a large scale. Should the trial prove successful, it is hoped to issue to tropical countries dried vaccine instead of the lanolinated lymph used at present. The dried vaccine would also be useful for epidemic reserves.

These and many other investigations are mentioned in a report that sets a standard in meiosis.

MÉNIÈRE'S DISEASE

IN 1861 Prosper Ménière,[1] a French physician, reported the case of "a girl who, journeying on the box seat of a stage-coach, became as a result of the cold suddenly and completely deaf." Her main symptom was vertigo, and she died on the fifth day. Necropsy showed a "red, plastic matter, a sort of bloody exudate" in the inner ear. Many years later Hallpike and Cairns[2] found in 2 cases of Ménière's disease dilatation of the whole of the membranous portion of the inner ear—so-called hydrops of the labyrinth. This change has since been repeatedly confirmed; but its cause is still undecided. The suggested causes include disturbances of water and salt metabolism, vitamin deficiencies, allergy, and toxic labyrinthitis from a septic focus. According to the belief, the patient is deprived largely of fluid and wholly of salt, fed on vitamins or filled with anti-histamine drugs, or asked to submit to operation for the drainage of infected sinuses or the removal of teeth or tonsils. With these various régimes relief is common, but cure rare; and simple sedation is the chief medical standby. Should the crippling attacks of vertigo continue, resort is had to operation, which in this country usually consists in destroying the labyrinth—and thus also the hearing on the affected side.

To the late E. R. Garnett Passe the paroxysmal nature of the attacks suggested a temporary disorder, which he thought might be a neurovascular disturbance, possibly arising from "underlying autonomic imbalance." Portmann and Despons[3] had reported hyperexcitability of the labyrinth after administration of drugs stimulating the sympathetic nervous system. Passe himself had observed gross dilatation of the vessels of the membranous semicircular canal during the fenestration operation, as a result of procaine block of the stellate ganglion. So, he reasoned, the labyrinthine vessels may go into spasm, and this may cause hyperexcitability; and the spasm might be relieved by interrupting the sympathetic pathways to the head and neck.[4] In a paper published posthumously Passe[5] reported that if stellate-ganglion block with 1% procaine subdued the tinnitus and improved hearing by air conduction, the patient was regarded as suitable for operation. In a first group of 45 patients the postganglionic fibres were interrupted by resecting the stellate ganglion; while a second group of 46 patients underwent preganglionic section. In the five years after operation over 60% of the patients in each group were completely relieved of their vertigo; and the condition of 33% was improved. These results have not been reproduced by other workers; and one wonders whether the Horner's syndrome which inevitably develops in patients who have had the stellate ganglion resected is not an even greater price to pay than the destruction of what little hearing may remain by the time that destruction of the labyrinth is undertaken. On the other hand, in the difficult cases of bilateral Ménière's disease, destruction of both labyrinths is to be avoided at almost any cost.

Rosen,[6] of New York, claims to have shown "for the first time since Ménière that the internal ear is not the exclusive seat of Ménière's disease." He had earlier reported that electrical stimulation of the chorda tympani nerve under local anæsthesia produced auditory impressions of hissing, buzzing, roaring, or ringing, and that such stimulation sometimes gave rise to severe rotatory vertigo. He had also described the effects of sectioning the chorda tympani, alone or together with the tympanic branch of the glossopharyngeal nerve, if the psychiatrist had planted nuts? The geriatrician should obviously have provided an elder, the obstetricians a plot of gooseberry bushes, and the venereologist a hawthorn because of its fruit and the number of pricks (intramuscular) which his calling demands. A bed of sweet peas outside the diabetic department might be rather old-fashioned, but what about a few sugar canes? The anæsthetists might well protest if offered a sycamore and ask for an olive, as they bring peace into the midst of turmoil. The surgeons could have any sort of tree that provides barber's poles, possibly an ash though as stools are made from this the pædiatrician has prior claim. The orthopods could have roses on account of the fruit. Dermatology might be represented by an eczemous tree (useful on Dec. 25) well covered with lichen. The hæmatologist could look up from his rhesus grouping to see a monkey puzzle of another sort, and the pathologists would find something with a lot of dead wood outside the mortuary. Aspens might be shared by the neurologists, who deal with the shaking palsy, and the general physician and his thyrotoxic patients. Any G.P. who needed a quiet life could plant an apple, and night sister might provide a cocoa plant. The urologists should try ground-nuts, bladder campion or possibly some of the stone fruit. The administrative officer from headquarters could be invited down to put in a large box bush as rulers are made of its wood. Those who say that box is a euphemism for coffin would be asked to keep their mouths shut. We would welcome a contribution from the Editor of *The Lancet*, and he no doubt would choose a blue cedar, as we understand that that is what pencils are made from.

* * *

The frequent clotting of London traffic during these last few weeks has given rise in pathological circles to the fear that it may stop altogether through coronationary thrombosis.

* * *

A *perambulation* of pædiatricians seems an apt collective noun, though we were by no means pushed around when members of the local pædiatric club inspected a veterinary research unit last Saturday afternoon. Indeed, we were so interested that we abandoned the toddler's gait customary on these occasions, and fairly gambolled round the laboratories and grounds.

The magnificent bulls for artificial insemination attracted most attention. Lest we should imagine, however, that there are no problems in the bovine Welfare State, we were told of difficulties which do arise. For instance, spermatozoa whose ardour has been cooled during months of frustration in the ice-chest sometimes take it on themselves to go backward *au moment critique*.

Vets vie with even the most recently fledged pædiatricians in "cubicilisation," and they are far in advance of obstetricians in their devotion to the antenatal care of fathers, a prospect which produced envious comment from the males in our party—and some wholly male pædiatricians do, somewhat anachronistically, persist.

What would an older generation have thought of the fact that we saw not a single horse during our visit? We did, however, see three dogs, though they were visitors and not inmates. We were also informed that when Dartmoor ponies are turned loose in lush grass they tend to develop dermatitis, owing to the unaccustomed high level of chlorophyll in their diet. Clearly, we shall have to watch those children who use the modern, widely advertised toothpastes.

In the museum two exhibits astonished us. One was an example of osteopetrosis, which was casually attributed to virus infection; the other, a specimen of muscular dystrophy, which is regularly cured with methylene-blue. On Monday morning I expect to see a crowd of would-be therapeutists in the records department of the children's hospital, anxiously looking up names and addresses in the diagnostic index of patients.

He is wise who knows that he
Dust has been and dust must be
But a fool is he who must
Fill the interim with dust

Letters to the Editor

ONE-STAGE PROTHROMBIN-TIME TEST

SIR,—It is being gradually recognised that the simple one-stage prothrombin-time test was largely responsible for bringing blood clotting out of the doldrums and confusion into which it had been plunged by reckless theories promulgated during the first third of the present century. So great was the bewilderment that the very existence of prothrombin was at times denied. It is beginning to appear as if the cycle of confusion is about to be repeated. The clear concept of prothrombin as a constituent of the blood which becomes diminished by depletion of vitamin K or after the administration of dicoumarol is gradually being dimmed by the introduction of a multitude of new factors such as proconvertin, factor VII, and *co-thromboplastin*. As a result of this trend, the one-stage prothrombin-time has again become the target for condemnation. To be sure, its clinical value and reliability is no longer denied or questioned, but now the accusation is that it does not measure prothrombin. The statement in your editorial of April 25 that "The use of the Quick one-stage clotting test (the doubts about the 'prothrombin' it measures have, we suppose, made 'prothrombin-time' out of order) . . ." epitomises the views that at present seem to be in the ascendancy.

Before dismissing summarily this test as a quantitative measure of prothrombin, it may be judicious to reconsider it in the light of some recent findings, particularly those on the prothrombin in the blood of the newborn infant. As is well known, when the prothrombin is determined by the two-stage method, it is found to be 30% or less in spite of a normal prothrombin-time. It was in a vain attempt to explain the paradoxical results of the two-stage method that hypothetical prothrombin converting factors were first introduced. Yet one is still waiting for concrete proof that such agents exist as primary factors in circulating blood. Attempts to show their presence in blood in the newborn have failed.[1] The findings in infants' blood can be satisfactorily explained without introducing accelerator factors. The blood of both newborn and adults contains the same concentration of active prothrombin, which accounts for the normal prothrombin-time in both bloods.[2] In adults, however, the blood contains in addition a high concentration of prothrombinogen (inactive prothrombin), which is absent in newborn blood; consequently, the total prothrombin which is measured by the two-stage method is much lower in newborn than in adult blood. No agent such as factor VII need be postulated to explain the normal prothrombin-time of infant blood.

It seems reasonably certain that failure to recognise the existence of prothrombinogen in human blood has been largely responsible for the present array of hypothetical accelerator factors. In a recent publication[3] we have shown that the prothrombin-time remains a reliable measure of prothrombin, provided the procedure is carried out as originally outlined. The findings which are now attributed to converting factors can probably all be more simply re-interpreted by the conversion of prothrombinogen to active prothrombin.

If the reliability of the one-stage method is unjustifiably undermined, the interpretation of the prothrombin-consumption test would likewise become a hopeless jumble, despite the fact that this test furnished the first practical explanation for the coagulation defect of both hæmophilia and thrombocytopenia. It would be most unfortunate if progress in the thromboplastin-deficiency states were arrested by a deluge of new theories and in 14 cases of Ménière's disease; in 11 the attacks of vertigo ceased. These results, he claimed, led to the "inescapable inference that the internal ear is not the *sole . . . portion of the nervous system from which the* symptoms of Ménière's disease derive [and] that these symptoms may be mediated by way of sonic and equilibratory afferent fibres in the chorda tympani." Rosen now describes 2 cases of what he believes to be Ménière's disease, both unilateral and both with dead labyrinths on the affected side. The persistence of "Ménière attacks" despite a dead labyrinth he takes to be further evidence of some extralabyrinthine pathway by which symptoms are produced. In both cases the vertigo ceased after section of the chorda tympani. Of these 2 patients, 1 had had a fractured skull, after which "there was total absence of caloric response and total loss of hearing" on the affected side; in the other case the symptoms developed after mumps. Both fracture of the skull and mumps are recognised causes of unilateral perceptive deafness.

[1] Quick, A. J., Hussey, C. V. *Proc. Soc. exp. Biol., N.Y.* 1953, 82, 449.

[2] Quick, A. J., Murat, L. G., Hussey, C. V., Burgess, C. F. *Surg. Gynec. Obstet.* 1952, 95, 671.

[3] Quick, A. J., Hussey, C. V. *New Engl. J. Med.* 1953, 248, 624.

Fowler and Zeckel [7] pursue the search at a higher level. They declare that "certain personality types tend to develop tinnitus and perhaps vertigo under stress." The attacks, they find, are associated with certain types of life-stress, including personal antagonism, sexual abstinence in the male, sexual conflicts in the female, and death of a near relative. Fowler and Zeckel do not, however, give convincing evidence of Ménière's disease in the 23 cases on which their report is based. In those cases where the deafness is described in detail, it is said to have been for low tones; whereas in Ménière's disease the loss is for high tones.

It cannot be said that great strides have been made in the attack on this troublesome disorder.

HALLUX VALGUS

CORRESPONDENTS, commenting on a leading article,[8] have expressed the view that the badly shaped shoe is the main cause of hallux valgus. This is not the only cause—even in some peoples habitually going barefoot hallux valgus is not uncommon [9]—but the evidence that shoes force the toes out of line is difficult to refute, and their deforming action is almost certainly the major ætiological factor in most cases of hallux valgus.

If we accept this, what are we going to do about it? There has long been a tendency to reverse the Victorian custom by which the foot had to fit the shoe rather than the shoe the foot. Knowles [10] describes an instance of an adult with mild hallux valgus who for three and a half years wore shoes, made on a special last, which were basically triangular and had a perfectly straight inner border. Foot symptoms were immediately relieved, and the degree of hallux valgus was materially lessened. In this country Mr. Pratt [11] has been pressing for the introduction of shoes with a straight inner border.

Shoes with a truly straight inner border are difficult to obtain; but some makers [12] specialise in shoes with fairly stringent inner borders. There would be, of course, no difficulty in producing such shoes if the necessary lasts existed. The trade, through the knowledge gained by the British Boot, Shoe, and Allied Trades Research Association, is well aware of the physiological need for these shoes. But two things militate against such a change. First, it would be very expensive to change every last; secondly, few people—and hardly any women—would buy the new shoes. The pioneer manufacturer of this type of shoe will meet a small demand from the highly foot-conscious; but unless the change is introduced simultaneously throughout the civilised world, with the support of massive publicity, we see no prospect of the demand increasing. It is not that the new shape of shoe would be intrinsically ugly; in such matters it is simply a matter of what one is used to (vide men's hats). The change could, we suppose, be introduced step by step if the trade and their designers agreed that they would gradually make shoes with straighter and straighter inner sides. But what stimulus is there for them to follow this costly course, so much against their immediate interests? There is only one rapid solution. At the command of a Schiaparelli or a Christian Dior waist-lines rise or fall. Cannot a shoe designer be groomed to similar stardom? Of course the trade for its part may be waiting for a lead from the medical profession: but what form should this lead take?

SPONTANEOUS PNEUMOTHORAX

IN the early 19th century when Itard [1] first used the word "pneumothorax" and Laennec published his excellent description of the condition,[2] the qualification "spontaneous" was not used. Subsequently—for instance, in Powell's textbook of 1893 [3]—this qualification was applied to pneumothoraces where no cause could be found, as opposed to those associated with pulmonary tuberculosis or other disease. But when the production of a pneumothorax became a therapeutic procedure, all other varieties, except traumatic, were grouped as "spontaneous," since they arise through natural processes. Unfortunately, the group name is now commonly used for a single subgroup. Thus, a recent report by DuBose and others,[4] although entitled "Spontaneous pneumothorax: medical and surgical management," deals only with pneumothoraces unassociated with active pulmonary inflammation or neoplasm.

Laennec knew that air could be present in the pleural cavity without any perceptible change of structure of the pleura; and it was later recognised that a pneumothorax could occur in apparently healthy people.[5] In 1932 Kjaergaard [6] defined the condition as one in which there is a pneumothorax "without demonstrable cause in healthy individuals . . . in whom the lesion is not accompanied by fever or by [a clinically recognisable] pleural effusion." He called this "pneumothorax simplex"; others have named it "benign" or "idiopathic." Kjaergaard's definition is no longer adhered to, and the term is now applied even to cases where a cause for the air leak has been found. For instance, Brock [7] described "recurrent and chronic spontaneous pneumothorax" in 71 patients where a probable cause was discovered in all but 6; there were 25 with generalised or bullous emphysema, 11 with solitary or multiple cysts, 15 with small apical bullæ, and others with apical scars, pleural tears, or minute subpleural air-bubbles. DuBose and others found radiographic evidence of bullous emphysema in 57 of their 73 patients. This is a surprisingly high proportion, even in a series of patients ill enough to be admitted to hospital; the frequency of radiographically detectable pulmonary abnormalities in all cases of simple pneumothorax is probably very much less. As the majority have only one mild attack, which does not warrant extensive radiographic or thoracoscopic investigation, a cause will be found in only a few; and thus most cases will still fall within Kjaergaard's definition. But if a lesion seems with reasonable probability to have caused the pneumothorax, it would seem worth while removing the case from the category of simple spontaneous pneumothorax and classifying it according to the cause.

TREATMENT OF HYPERTENSION

SIR,—Your annotation of April 25 reviewed with admirable brevity one side of this topic It left other aspects barely mentioned These can be approached through the viewpoint of 1933 We had then virtually no good hypotensive drugs We assumed that in perhaps 95% of cases the hypertensive needed his high arterial tension to provide adequate circulation to his vital organs (to what extent we were emulating the fox contemplating the desirables beyond his reach I cannot say) The past twenty years are noteworthy for the accumulation of data which warrant the abandonment of that concept, but many practitioners, in my country at least, are not aware of this

Perhaps the early work with thiocyanates was responsible for the beginning of the collapse of the concept In those few cases where irregularities of excretion, skin rashes, &c, were long enough delayed (by blood-level control or by good luck) real reductions in blood-pressure were shown to be well tolerated.[1] Soon the results of sympathectomy in favourable cases showed that many patients could function normally at much reduced arterial pressures The revival of *Veratrum viride* which followed the preparation of dependable, purified, and standardised extracts contributed similarly, since it quickly became clear that parenteral administration would strikingly lower the blood pressure of virtually 100% of hypertensive patients[2–6] At the resulting lower levels of blood pressure, which were often within the normotensive range, these patients could walk about and experienced no postural hypotension, and no embarrassment of cerebral, renal, or hepatic function The presence of a slow heart rate emphasised that normal function in the hypertensive at lower pressure was not gained at the expense of increased cardiac activity Despite their unphysiologic mechanism, hexamethonium salts have likewise contributed evidence of the capacity of the hypertensive to get along with reduced pressure

A direct result of this alteration of concept has been the enhancement of value attached to agents reducing pressure in individual cases Much improvement can be gained for certain patients from particular drugs[6, 7] It becomes important now to stop rejecting drugs which on oral administration effectively lower hypertensive blood pressures in only a limited percentage of cases We need to screen the active hypotensive agents in each patient in an orderly way, to find out which drug acts best for him We need to weigh the improvement the patient obtains from therapy against the dangers of toxic actions and against the discomforts of side actions produced by each drug Recently it has become clear that combinations of these drugs increase the percentage of patients who will respond and make possible reduction in discomfort due to side actions[8, 9]

The past ten years have focused attention on four agents worth screening in this orderly manner. Of these, three are drugs of great potency The fourth, *Rauwolfia serpentina*, is a basal agent[10, 11] Rauwolfia's mild action, its vagotonic effects, its freedom from side-actions, its ease of management consequent on low increment of response with dose (increasing dosage beyond the minimal effective produces neither fall in blood-pressure nor severe side effects), and very low toxicity combine to make it a basal hypote analogous to the ideal basal anæsthetic (nitrous o Rauwolfia, like veratrum, requires careful identifica extraction, and standardisation if its advantages to be obtained fully 'Rauwiloid' is a prop compound that may fulfil these criteria

The three full-potency hypotensives, while im are far ahead of classical substances Your anno made no mention of standardised *Veratrum* extract ('Veriloid' is an example) *Oral* tion of this agent deserves mention because it is safest of the three (no risk of organ toxicity, w margin against lethality), and because it will pro excellent results in 20–40% of patients[12] Its outsta disadvantage is the narrowness of the range be good hypotensive effect and emetic side action, makes management difficult The spread be hypotensive and emetic doses appears to be wi by combination with rauwolfia[8] Thus the percen of patients controlled by veratrum may be improved

From hexamethonium salts one can obtain the gre hypotensive action Acknowledging the side act and dangers mentioned in your annotation, recent w has revived hope that these compounds can be by mouth, since rauwolfia apparently can reduce required dosage and the incidence of side actions[9]

Hydralazine is a useful agent despite tolerance and unpleasant side actions of headache and tach but the risk of toxic effects (drug rash, drug possibly agranulocytosis[13]) must be weighed C tion with rauwolfia and even with hexamethonium from recent reports, to offer much advantage

In summary, I do not agree that the immediate pr pects for helping the individual hypertensive are poor If we use the tools now available against disease, our patients will benefit in proportion to skill

POLIOMYELITIS

SIR,—The case described by Mr Hyman (April 2 exemplifies the danger of over-exertion during recovery from poliomyelitis I do not agree with Dr Ritch Russell (May 2) when he brushes aside *too vigoro* exercise as the cause of the deterioration of muscle power in this case

Between the antiquated method of rigid splintin and exercises to the point of fatigue there is such range of possible variations that it is difficult for the le experienced to decide which to adopt In the subacut phase it is difficult to estimate from the, sometimes scanty, symptoms the stage of the lesion

With regard to the handling of affected limbs I try to avoid the muscles of, for example, a painful calf being pressed by the "dead weight" of the tibia In a few cases of very painful calves I have used what might be termed an "air cushion *gutter* splint," consisting of two inflated lengths of bicycle inner tubes These tubes are glued with latex to a length of 'Sorbo' in such a way as to form a gutter with varying width according to the shape of the calf Thus the lower leg is gently supported at both sides of the midline from the heel to the back of the knee, the midline itself remaining free from any pressure A layer of gauze cotton wool is placed on the rubber to prevent condensation Any device can be added as a foot support I have found very tender lower limbs surprisingly comfortable with such an arrangement

RESULTS OF A QUESTIONNAIRE CONCERNING CONTROLLED HYPOTENSION IN ANÆSTHESIA

L. JENNINGS HAMPTON
M.D. Pennsylvania
DIRECTOR OF ANESTHESIOLOGY, YALE UNIVERSITY SCHOOL OF MEDICINE

DAVID M. LITTLE, JUN.
M.D., Harvard
ASSISTANT CLINICAL PROFESSOR OF ANESTHESIOLOGY, YALE UNIVERSITY SCHOOL OF MEDICINE

DURING the past few years the problem of excessive bleeding during surgical operations has been the subject of numerous investigations. The problem is scarcely new, and for many years surgeons and anæsthetists have found a solution in the use of chloroform anæsthesia, high spinal analgesia, or the meticulous posturing of the patient so that the operation site might remain superior. Gardner (1946) introduced arteriotomy by which blood was withdrawn from the patient preoperatively and later was partly or completely replaced in the same manner at the end of the operation, or even during the operation if necessary. Such preoperative reduction of the amount of circulating blood lowers the blood-pressure and causes peripheral vasoconstriction; and, when it is combined with the proper positioning of the patient, the net result is the reduction of bleeding at the site of operation. A more physiological approach was total sympathetic block (Griffiths and Gillies 1948). In this method the blood-pressure is reduced by spinal anæsthesia to achieve paralysis of the entire efferent sympathetic outflow. Gillies (1952) has stated that this technique is without doubt "physiological trespass" but has assumed that the arteriolar dilatation guarantees normal oxygenation of the tissue cells, and that the decreased cardiac output inherent in the technique is compensated for by the decreased peripheral resistance and therefore the decreased work of the heart. Proper posturing of the patient is again an essential feature of the control of bleeding, as it is in all methods of "controlled hypotension." The introduction of the methonium compounds (Barlow and Ing 1948, Paton and Zaimis 1948) provided a simple method of ganglionic blockade merely by injection, and led to the widespread use of induced hypotension for the control of excessive vascular bleeding in the field of operation, again in combination with proper positioning of the patient (Davison 1950, Enderby 1950).

AIMS AND EXTENT OF QUESTIONNAIRE

These techniques of induced hypotension for the control of excessive bleeding and the production of a relatively bloodless operation site have become increasingly popular among both surgeons and anæsthetists in the British Isles. Only within the last year or so has the method been used to any great extent on the American continent. Within this same period alarming warnings have been sounded, for it appears that certain complications of the technique have been much more common than were previously supposed (*Anæsthesia* 1952, Davison 1952, *Lancet* 1952). Knowledge both of these disasters and of the beneficial effects possible for a given patient are essential to the proper assessment of the technique and a true estimate of its position in anæsthesia and surgery.

Since the experiences of the anæsthetists in the British Isles with the technique of "controlled hypotension" greatly exceeds that of the anæsthetists on the American continent, questionnaires were sent to 602 members of the Association of Anæsthetists of Great Britain and Ireland in an attempt to obtain utterly anonymous, but unbiased, reports of the results of the technique, most particularly those fatal and non-fatal complications that might have been observed in its use. In the belief that the results of this questionnaire might be of some interest to those from whom the results originated, and with a feeling of deep gratitude toward those physicians of integrity who took part in this investigation, we submit this report.

Of the 602 questionnaires sent, 289 have been completed and returned up to now. This constitutes a return of 48%. The questionnaire was poorly worded, in certain instances; hence many of the figures are only approximate, and some editorial corrections became mandatory. For these reasons no statistical significance can be attributed to the results. These results do, however, indicate that "controlled hypotension" has been widely used, that complications have followed its use, and that deaths have been associated with, if indeed not due to, the technique.

RESULTS OF QUESTIONNAIRE

Each question from the questionnaire is printed below in its original wording, together with the results derived from an analysis of the 289 returned questionnaires:

(1) *Have you employed "controlled hypotension" to secure a bloodless operating field during surgical interventions?*

Yes	170
No	111
Yes, but have abandoned technique	8

(2) *What technique have you employed to obtain "controlled hypotension"?*

Arteriotomy	5
Spinal	51
Methonium compounds	166
Others (please state):	
Posture, plus deep ether or Pentothal	11
Veratrum viride	1
Chloroform	5
Amyl nitrite	1
Extradural block	7
Intercostal and sympathetic blocks	1
Local injection with adrenaline	2
Pronestyl with methonium compounds	1
Venesection	1
Various vasodilator agents	1
Barbiturates and Pentothal	1
Pethidine	1

Some anæsthetists used more than one technique.

(3) *In approximately how many cases have you used the technique?*

Arteriotomy	206
Spinal	6922
Methonium compounds	11,979
Others	2018
Total cases	21,125

(4) *What level of blood-pressure do you strive to attain?*

	Anæsthetists	*No. of cases*
60 mm. Hg or less	44	4571
60–80 mm. Hg	54	6847
70–80 mm. Hg	50	5727
80–90 mm. Hg	17	1392
90 mm. Hg	4	666
100 mm. Hg	3	232
Not stated	6	1690

(5) *Do you employ posture as a factor in obtaining a bloodless field?*

Yes	152
No	9
Sometimes	17

(6) *Do you employ vasopressor agents to return the blood-pressure toward normal?*

Yes	38
No	50
Sometimes	90

I add one word about the transfer of poliomyelitis its from fever hospitals to other units for further nent Transfer after 3 weeks as now practised l be regarded as an expedient to ease the burden e fever wards—not as justified from every point w Opinion on the danger of spread of infection this period is not yet unanimous, and, even after first 3 weeks, treatment is still—except in very cases—restricted by pain and the general afters of the illness The later the patient is exposed ercises to the point of fatigue, the better

THE NURSE'S RESPONSIBILITY

IR,—Your leading article of June 6 and the subsequent ers from Dr R E Smith (June 13) and two members the nursing profession (June 20) cover very rough und and anyone who joins in the discussion may well nble!

urely this new problem of how much a nurse should expected to do in the management of the sick patient et another expression of the increasing fear of litiga- which is dominating hospital policy and regulation fessional bodies in medicine and nursing, no less n the many hospital authorities, are seeking to tect themselves from persecution by their patients welter of circular letters issued by regional boards l by the Ministry itself is an endeavour to manage whole of medicine by regulation If the nursing ff—that is the trained staff—are to be restricted to t some would call the "maternal" aspects of sing, who then is prepared to undertake the scientific rk involved in modern treatment?

There is a gross shortage of house officers, consultant ncs are overloaded, waiting-lists are large, and many hospitals lack of operating-theatre accom dation restricts the turnover Medical treatment is m-work, and any member of the team, no matter at his or her official training has been, must surely be pared to undertake such tasks as are delegated by leaders of the team We are repeatedly hearing rnings that the nurse must not be turned into a on-registered doctor," but modern surgery in particular demands that skilled nursing must be based on scientific understanding Much of the nurse's interest in her work in the past has been lost by "parrot-wise" teaching in which the nurse has learnt the answers to questions she may be asked in examinations, but has had no real understanding of the meaning and purpose of her actions

Those who accept any part of the treatment of the sick must also accept responsibility which cannot be defined by rules and regulations Herein lies the difference between the clinical staffs of our hospitals and the lay administration, which, though it may fail to provide the personnel and facilities for adequate treatment, is always itself protected by the fact that it (the impersonal administration) has had no contact with, or personal responsibility for, the patient If the restrictive ideals which have now been suggested were put into practice, many of our hospital beds would be put out of action We are much dependent upon the work which our nurses undertake beyond their training syllabus, and indeed beyond the number of hours officially allotted for their duties Any suggestion of "working to rule" must never be allowed to come into our hospital service on the professional side, no matter how much we are *all* provoked by the many impositions placed on both medical and nursing staffs as the public and its legislators continue in their struggle to squeeze a quart into a pint pot

London S E 19 **D F ELLISON NASH**

IMMEDIATE RESULTS OF SANATORIUM TREATMENT

SIR,—In 1951[1] I described the results of treatment, judged by "sputum conversion," of male adult patients discharged from Colindale Hospital in the years 1938–50 These totalled 3332, but after deducting sputum-negative patients, and those whose stay was too short for conversion to be attained for three consecutive months before discharge, 2472 entered the survey

Up to 1947 the conversion-rate was below 29%, but it rose in 1948 to 36%, in 1949 to 55%, and in 1950 to 63% I attributed this improvement partly to the admission of less advanced cases, but mainly to the effect of streptomycin and *p* aminosalicylic acid

I can now bring the investigation up to date, by giving results for 1951 and 1952, during which 731 male patients have been investigated, of these 385 were sputum-positive and stayed long enough to satisfy the criteria for sputum-conversion The following is a summary of the results

Year	Sputum-negative	Sputum positive on admission		Converted	Total	% conversion
		Not converted	2/12-converted			
1951	170	64	10	111	185	60
1952	176	70	10	120	200	60

The conversion-rates of 60% attained for both years are slightly lower than for 1950 (63%), and, although I previously expressed the view that, as chemotherapy was now fully exploited, the curve was likely to flatten out, this actual fall, though slight, deserves some explanation especially in view of the introduction of isoniazid in 1952

The above summary shows that in 1951 and 1952 no fewer than 346 patients (47%) were sputum-negative In 1950 the corresponding proportion was 37% and in previous years it was 22% or less Of the 176 sputum-negative cases in 1951, 121 (68%) had been sputum-positive at some previous date, commonly shortly before admission, and of 100 consecutive admissions

---

(7) *What contra-indications do you consider exist to the use of the technique of "controlled hypotension"? Please state:*

Cardiovascular disease in general, or any thrombosis	48
Cerebrovascular disease	32
Coronary disease	62
Arteriosclerosis	51
Cardiac disease, valvular disease, angina pectoris, myocardial infarction, decompensation	46
Hypertension	43
Renal disease	48
Hepatic disease	8
Too old: more than 40–50 years	51
Too young: less than 16–20 years	30
Anæmia	18
Hæmorrhage, preoperative	10
Shock	18
Hypotension	22
Poor physical condition, dehydration, low blood volume, chloride loss, &c.	30
Type of surgery: "luxury," minor, &c.	55
Difficult posture required: non-Trendelenburg, steep Trendelenburg, lithotomy	9
Dangerous, inexperienced, slow, or old-fashioned surgeon	4
Inexperienced anæsthetists or difficulties in anæsthesia	14
Poor operating-room or postoperative facilities	6
Pulmonary disease	4
Neurological disease	2
Diabetes mellitus	4
Miscellaneous—obesity, pregnancy, acute toxic disease, &c.	15

(8) *Have you encountered any of the following complications? If so, please check opposite the complication, and state the number of times that each complication has arisen:*

Anuria	54
Oliguria	30
Cerebral thrombosis	20
Retinal thrombosis	2
Coronary thrombosis	15
Mesenteric thrombosis	0
Reactionary hæmorrhage	164
Delayed postoperative recovery	190
Difficulty with vision	126
Others (please state):	
Cardiovascular collapse	6
Cardiac arrest	6
Auricular fibrillation	1
Ventricular fibrillation	1
Sudden blood-pressure drop	5
Pulmonary embolism	1
Air embolism	1
Hypoglycæmia in diabetes	2
Persistent hypotension	3
Ileus	1
Paralysis of bladder	1
Casts in urine	3
Spinal arachnoiditis	1
Vague cerebral anoxic states	3
Postoperative mental confusion	3
Postoperative lassitude	4
Prolonged drowsiness	3
Painful back and legs due to position	7
Total (1 in 38 cases)	553

(9) *Have you encountered mortalities with the use of the technique of "controlled hypotension"?*

Yes	37
No	130
No, but have knowledge of deaths	11

If "Yes," please state the number of cases and the presumptive causes of death:

Renal failure	8
Cerebral thrombosis or cerebral anoxia	11
Coronary thrombosis	7
Cardiac arrest or failure	6
Reactionary hæmorrhage	2
Mismanagement (high spinal)	2
Over-heparinisation (arteriotomy)	1
Sudden death, cause unspecified	1
Death, cause not stated	1
Miscellaneous (4 probably unrelated)	7
Total (1 in 459 cases)	46

SUMMARY

Questionnaires were sent to 602 members of the Association of Anæsthetists of Great Britain and Ireland concerning the use of "controlled hypotension" in anæsthesia. Of these questionnaires 289 (48%) were completed and returned, 178 anæsthetists reporting the use of the technique in more than 21,000 cases.

The results of this questionnaire should by no means be construed as an indictment of "controlled hypotension." When wisely used, in the carefully selected case, for an urgent and rational indication, the technique may prove most beneficial for a given patient.

However, a mortality-rate of more than 1 in 500 indicates that this technique is potentially dangerous, and it should therefore never be used in the absence of a specific and urgent indication or for the convenience of surgery. Obviously, it must never be used by the unwary, the unknowing, or the unskilled. Further, it is specifically contra-indicated in certain conditions; these contra-indications must be respected.

"Controlled hypotension" is indeed "physiological trespass"—the anæsthetist can never afford to forget this fact.

We are indebted to Dr. Georgina Y. Goodwin, resident in anesthesiology, for invaluable assistance in the tabulation of the figures.

THE PRACTITIONER IN THE N.H.S.

The Minister's Appeal

ADDRESSING the Annual Conference of Local Medical Committees, held in London on June 17, Mr. IAIN MACLEOD, the Minister of Health, said that when Sir Stafford Cripps in 1950 found it necessary to impose a ceiling on expenditure on the National Health Service, it became obvious that, with costs of all kinds tending to rise, we should sooner or later be forced into the position of selecting priorities. This was a problem that went wider than the health service.

"I made a rough calculation a week or two ago which told me that I could justify to the House of Commons and to the country, if medical need alone were the criterion, a capital programme of something like £1000 million, taking no account of the many hundreds of millions of pounds on maintenance expenditure that would involve in other years. But so, of course, could the Minister of Education in her field; so could the Home Secretary with all our needs for new prisons and institutions to replace some of our outmoded buildings; so could the Minister of Housing and Local Government and the Minister of Transport for the roads and so on."

If too much was spent in any particular field there would be all the less available for the more essential services.

THE DRUG BILL

Were we getting full value for the £40 million spent on prescriptions by general practitioners? (Taking into account the whole range of drugs, medicines, and appliances the figure was more like £60 million.) Partly because of fog, flood, and influenza, it had been very taken at random at least 60 had received "chemotherapy" either at home or in other hospitals before admission In other words, those cases which were amenable to conversion by bed rest and chemotherapy had been converted before admission, leaving a more resistant group to enter this survey

A factor hindering improvement in conversion-rates is the number of middle aged (over 45) patients who, because of delayed diagnosis with resulting irreversible changes in the lungs and chronic respiratory disability characteristic to their years, and consequent unsuitability for surgery, often constitute insoluble problems in treatment My 1951 paper showed that the chances of conversion regularly receded with advancing years, and the new figures, though small, support the previous findings

CONVERSION BY AGE GROUPS 1951 AND 1952

Age (years)	Not converted	2/12 converted	Converted	Total	% conversion
Under 20	5	1	11	17	
20–29	30	6	94	130	72
30–39	37	5	67	109	61
40–44	16	2	22	40	55
45 and over	46	6	37	89	42
Totals	134	20	231	385	60

In view of changing fashions in treatment, it may be again of interest to note the methods by which conversion was attained, but the increasing complexity of treatment makes classification ever more difficult The accompanying table indicates the broad lines by which success was achieved Comparing the two years, the second shows fewer conversions by artificial pneumothorax and thoracoplasty, a static number by plombage, and more conversions by resection and especially (perhaps surprisingly), by pneumoperitoneum, which was of course associated in most cases with chemotherapy. Over the previous twelve years the main treatments producing conversion were artificial pneumothorax 35%, routine treatment 21%, and thoracoplasty 17% Owing to the widespread use of chemotherapy and the greater variety of surgical treatment, conversions by routine treatment alone are now very few, but the sanatorium régime nevertheless remains, for all patients, the fundamental basis of treatment

Summary —In this investigation sputum conversion is held to have taken place when the sputum has been found free from tubercle bacilli on direct examination and culture, for the three consecutive months preceding discharge (Patients converted for the final two months only are also recorded but are considered as unconverted) Of 385 sputum-positive patients treated at Colindale in 1951 and 1952 231 (60%) underwent conver Of the 346 sputum-negative patients admitted du this period, approximately 68% had been sput positive shortly before admission they had under conversion mainly by "chemotherapy," leaving a tively resistant group who were still sputum posi when admitted Of the sputum-positive patients 2 were aged 45 or over—the group least susceptible conversion Comparing the last two years at Coln more conversions have been obtained by resection pneumoperitoneum, and fewer by artificial pneu thorax or thoracoplasty

Colindale Hospital,

MEDICAL HISTORY OF THE SECOND WORL WAR

SIR,—In your review (June 13) of the *Medical Hist of the Second World War* you remark that the book unlikely to raise the pulse rate of many of those served under the motto *Per arduis fidelis*

I think it possible that the blood pressure of m of those who served in the R A M C (at any rate of th who have had the advantage of a classical educati may be raised, when they see their noble motto so vi misquoted

Wakefield

G E MACALEVLY.

*** We apologise for our inadvertence The mo is, of course, *In arduis fidelis* —ED L

OBSERVATIONS ON PEPTIC ULCER

SIR,—It is not for me to discuss the physiologi aspects of Dr Csato's original and stimulating let (May 16) But may I draw attention to the cruc change of attitude towards a certain interesting group diseases implied in his approach ?

The emphasis he places on periodicity as opposed t the static evidence of the X ray plate has a relevan far wider than merely to the treatment of peptic ulce It adds, in fact, the fourth dimensional quality o time/motion to the consideration of those diseases i which periodicity plays a major part As he rightl claims, periodicity is a factor which has often been noted, but in treatment consistently ignored

Among philosophers Heraclitus, echoed centuries late by Bergson, has compelled recognition of time and motion as prime factors in the structure of the Universe, and it is now some time since physicists discovered, to their temporary confusion, that the weights of certain things were different when in motion than when at rest But medicine, as far as treatment is concerned, doggedly persists in its static, three dimensional approach

TABLE V—WORK DONE BY THE MEDICAL OFFICER

—	Children not needing treatment					Children needing treatment		Total
	Routine examination only	Mother reassured	Mother advised about:			Treated at clinic	Referred	
			Feeding	General management	Priorities and certificates			
ningham ..	10·5 % (*58*)	16·6 % (*92*)	25·7 % (*142*)	6·5 % (*36*)	1·8 % (*10*)	22·1 % (*122*)	16·8 % (*93*)	100 % (*553*)
cley	11·4 % (*62*)	15·7 % (*85*)	17·5 % (*95*)	4·6 % (*25*)	7·7 % (*42*)	33·7 % (*183*)	9·4 % (*51*)	100 % (*543*)

Of the 43 children who attended in Birmingham, 17 re referred by health visitors to the doctor, whose rk consisted of routine examination of the child and, here necessary, reassurance of the mother (4), advice out feeding, management, or priorities (6), treatment), and referral (3). In Coseley, on the average 52 mothers tended with children, of whom 14 were referred to the octor. The work of the doctor consisted of immunisaon (5), examination and reassurance (2), advice (3), eatment (3), and referral (1). The work of health isitors was not examined in detail; it comprised advisory ervice, routine weighing, simple treatment, and selection f cases for referral to the medical officer.

VALUE OF THE SERVICES

The work of the clinics evidently still consists essentially f the four traditional services: food distribution; advisory ervice; routine examination; and medical attention. t is difficult to assess their value, which has recently been uestioned (Banks 1952), since no objective data exist by hich their work may be measured. Their development as coincided with a reduction in mortality-rates; but n the same period there have been other changes likely o improve the health of children—for example, a decrease n mean family size, improvement in the standard of living, nd, more recently, the introduction of effective therapy. We must therefore rely on a common-sense appraisal of ach type of service. Probably no-one would question the importance of the food distribution and medical attention, but the advisory service and routine examination require further discussion.

TABLE VI—ADVICE GIVEN TO MOTHERS ABOUT FEEDING

—	Birmingham	Coseley
Veaning	17·6 % (*25*)	16·8 % (*16*)
laintenance of breast-feeding ..	13·4 % (*19*)	23·2 % (*22*)
upplementary, complementary, and test-feeds	20·4 % (*29*)	15·8 % (*15*)
egurgitation, wind, looseness, and constipation	12·7 % (*18*)	7·4 % (*7*)
ther and unspecified problems ..	35·9 % (*51*)	36·8 % (*35*)
Total	100 % (*142*)	100 % (*95*)

Whatever reservations one may have about the usefulness of some of the activities currently promoted as health education, there can be little doubt that the instruction of an uninformed mother by an experienced health visitor or doctor is valuable. Breast-feeding, bowel-training, preparation of artificial foods, and weaning are not matters in which it is possible to rely either on a mother's instinctive good sense, or on the advice given by friends or relatives. A few women in favourable circumstances have received suitable instruction elsewhere—mainly from private doctors—but most women have obtained it from clinic medical officers and health visitors, or not at all.

TABLE VIII—CONDITIONS REFERRED ELSEWHERE

Conditions	Birmingham	Coseley
Bronchitis, pertussis, early pneumonia, &c.	10·8 % (*10*)	41·2 % (*21*)
Diarrhœa and vomiting, threadworms, pyloric stenosis, &c.	8·6 % (*8*)	11·8 % (*6*)
Eye deviation, conjunctivitis, blepharitis, &c.	11·8 % (*11*)	19·6 % (*10*)
Dental caries	15·1 % (*14*)	2·0 % (*1*)
Otitis media	16·1 % (*15*)	7·8 % (*4*)
Hernia or phimosis	4·3 % (*4*)	3·9 % (*2*)
Other conditions (orthopædic and skin conditions, cellulitis, injuries, P.U.O., &c.)	33·3 % (*31*)	13·7 % (*7*)
Total	100 % (*93*)	100 % (*51*)

On the value of routine examination opinion will inevitably be divided. Regular medical inspection has always been a feature of the child-welfare movement, and is generally believed to serve two purposes—early detection of remediable disabilities, and collection of anthropometric data. Our own view is that the data collected have hitherto been of little scientific value, but

TABLE VII—CONDITIONS TREATED AT CLINIC

Condition	Treatment	Birmingham	Coseley
Umbilical hernia	Strapped	11·5 % (*14*)	29·5 % (*54*)
Umbilical polyp	Copper sulphate, silver nitrate	3·3 % (*4*)	2·7 % (*5*)
Phimosis	Prepuce separated	15·6 % (*19*)	28·4 % (*52*)
oryza and bronchitis	Narist. ephed., or menthol	16·4 % (*20*)	3·8 % (*7*)
kin conditions (napkin and teething rashes, seborrhœa, impetigo, scabies, &c.)	Lot. calamin., ung. H.A.D., crem. zinc. et ol. ric., applic. benzyl benzoate	23·0 % (*28*)	10·4 % (*19*)
Gastro-intestinal conditions (diarrhœa, vomiting, constipation, flatulence, threadworms)	Tab. sod. cit., tab. hyd. c. cret., tab. gent. violet, milk of magnesia	13·1 % (*16*)	9·8 % (*18*)
Debility (post-operative, -portussis, -pneumonic, &c.)	Syr. ferri. phos. co., syr. ferri et ammon. cit., maltoline	7·4 % (*9*)	5·5 % (*10*)
Other (eyes, teething, maternal anæmia, &c.) ..	Ung. hyd. ox. flav., tab. ferrous sulph.	9·8 % (*12*)	9·8 % (*18*)
Total		100 % (*122*)	100 % (*183*)

TABLE II—PROPORTION OF CHILDREN REFERRED BY HEALTH VISITORS TO THE MEDICAL OFFICER

—	Children referred to M O	Children not referred to M O	Total
Birmingham	39 4 % (*553*)	60 6 % (*850*)	100 % (*1403*)
Coseley	26 8 % (*868*)*	73 2 % (*2367*)	100 % (*3235*)

**Of 868 children referred to the Coseley medical officer 325 immunised against diphtheria have been excluded from subsequent tables*

of children attending per session were 43 and 52 and the average numbers seen by medical officers 17 and 14 Table III gives reasons for referring children to the doctors (Children referred for immunisation in Coseley have been excluded) About a third had been sent for routine examination In both local authorities a child paying its first visit to a clinic is automatically referred for medical inspection, but after the first visit practice differs in Coseley children see the doctor again only by special request , in Birmingham they are referred for medical supervision about once in three months There is a considerable difference in the proportions seen at the request of health visitors (Birmingham 19%, Coseley 1%), which suggests that part of the work done in Birmingham by medical officers was performed in Coseley by health visitors

More than 40% of the children medically examined had been sent *to the medical officer at the request of the* mother Since the National Health Service Act has removed the economic reason, we asked why these mothers chose to consult the clinic medical officer rather than their own general practitioner (table IV) More than 40% of the mothers had not considered the possibility of consulting their own doctor A further 10% had attended the clinic to collect food or to have the child weighed, and, having some minor problem, " thought they might as well see the doctor there about it " The remainder (almost half) gave reasons suggesting dissatisfaction with their general practitioner service the surgery was too far away , a crowded surgery was no place for a child , afternoon consultation was more convenient , or the doctor was abrupt, rude, or too busy to make even a cursory examination

WORK OF THE CLINIC MEDICAL OFFICER

Table V gives details of the work done by clinic medical officers Some children (73 and 71 in Birmingham and Coseley respectively) had more than one service but we have considered only the more important service

Routine Examination —About 10 % of the work done by the medical officers consisted in routine examination of children so healthy and well-cared for that no advice was considered necessary That is to say, 120 of the 338 children submitted for routine examination (table III) were thought to need no service of any kind

Reassurance —About 16 % of children had minor ailments—sometimes real, sometimes imaginary—for which no treatment and little specific advice was needed (coryza, transient skin conditions, and minor general complaints)

Advice —About a third of the mothers (34 0 % in Birmingham and 29 8 % in Coseley) were advised about the feeding and general management of their Table VI gives details of the kind of feeding problem which advice was sought—e g , weaning, breast fee or complementary feeding Under " general ma ment " (table V) are included instructions conc napkin hygiene, clothing, physical activity, and bladder, and sleeping habits Also included " advice " in table V are cases in which the medical issued certificates or advised about priorities Birmingham and Coseley 1 8 % and 7 7 % were of this type In both local-authority areas chil were certified as fit to enter day or residential nur and notes were written to expedite hospital In Coseley the doctor, as medical officer of health, also concerned with the rehousing of families for med reasons, and with the issue of free infant food necessitous families

TABLE III—REASONS FOR REFERRING CHILDREN TO THE MEDICAL OFFICER

—	Routine examination		Specific request by				T
	First visit	Quarterly supervision	Clinic M O	Health visitor	Mother	Hospital or G P	
Birmingham	11 6 % (*64*)	16 3 % (*90*)	11 2 % (*62*)	19 2 % (*106*)	41 4 % (*229*)	0 4 % (*2*)	[illegible]
Coseley	33 9 % (*184*)		17 1 % (*93*)	0 7 % (*4*)	46 8 % (*254*)	1 5 % (*8*)	[illegible]

Treatment at Clinic —In Birmingham about a fift (22 1 %) and in Coseley a third (33 7 %) of children we treated at the clinic Table VII shows the conditions dea with—e g , umbilical hernia or polyp, phimosis, mil respiratory infections, and napkin and teething rash The official attitude towards treatment *in child* welfa clinics has always been that a child needing anythi more than the most trivial attention should be refer to his own doctor, and clinics in general stock only few simple medicaments

Referral —Finally, 16 8 % and 9 4 % of Birmingha and Coseley children respectively were referred elsewher for conditions similar to those met in the consulting roo of the general practitioner—e g , pneumonia, whoopin cough, diarrhœa and vomiting, conjunctivitis, otit media, and cellulitis (table VIII) Most of these patient (72 % in Birmingham, and 92 % in Coseley) were referre to their general practitioner ; a few were sent directly to hospital, or to local authority dental or remedial clinic

Discussion

We may summarise the results of the foregoin analysis of the work of child-welfare clinics as follows

In Birmingham, on the average 101 mothers attended each session, of whom 51 bought food at the branch food office, and 50 entered the clinic proper Of the 50 who entered the clinic, 7 attended without the child to obtain priority foods 43 attended with the child, of whom 20 came to have it weighed, 8 to get specific advice, and 15 to obtain priority foods Of the 15 who came for foods, 11 wished also to have the child weighed, and 2 to have advice about its management It is clear that whatever the official view of the clinic's function, the distribution *of cheap food* is still an important incentive for attendance

TABLE IV—REASONS GIVEN BY MOTHERS FOR NOT CONSULTING A GENERAL PRACTITIONER

—	Not considered by mother	Attending clinic for other reasons	Clinic hours or location more convenient	G P too busy	Advice wanted about need for consultation	No confidence in G P	Other and unspecified	Total
Birmingham	44 1 % (*101*)	11 1 % (*26*)	9 2 % (*21*)	5 2 % (*12*)	7 4 % (*17*)	21 8 % (*50*)*	0 9 % (*2*)	100 % [illegible]
Coseley	40 6 % (*103*)	10 6 % (*27*)	7 9 % (*20*)	5 9 % (*15*)	11 8 % (*30*)	21 7 % (*55*)*	1 6 % (*4*)	100 % [illegible]

* 9 Birmingham and 3 Coseley mothers had already consulted their general practitioners but were not satisfied with his advice

that most temporal and motionable of entities—the human organism. The real originality of Dr. Csato's contribution will not, I hope, be sidetracked as just one more therapeutic suggestion for a single ailment.

London, W.1. ALAN McGLASHAN.

HOSPITAL COSTING

SIR,—The letter from "Administrator" (June 20) calls for a response from me. I read with interest that he assumes that I am "unaware not only of the lessons of practical accounting but also of the important psychological advantages that can flow from purposeful accounting in terms of individual responsibility."

I had some ten years' experience of practical accounting, both in the profession of accountancy and in industry. During this period I became a chartered accountant, and subsequently engaged in reorganisational work in large-scale industry—particularly in connection with clerical routines. All this was years ago, but the essential problems are still much the same; punched-card routines, the problems of the unreliability of primary data in costing schemes (time-sheets, &c.), the difficulties of seeing the wood for the trees—these are still features of the accounting landscape.

"Administrator" appears to be defending the principles of cost-accounting against the ill-informed doctor; I sympathise with his imagined predicament, but I am sorry that he should thus misunderstand my article (May 16), for I am primarily interested in achieving real coöperation between doctors and administrators. His anxiety to defend himself against imaginary attack leads him to make criticisms which are I think unjust. I devoted some space to emphasising the need for extracting items of expense which were controllable by the individuals concerned, so that individual responsibility should be fostered; yet "Administrator" accuses me of being unaware of this necessity!

He considers that my object of "providing a corrective to any too-enthusiastic adoption of detailed schemes" is at variance with the title of my article; I cannot see this. This criticism would be valid only if my object had been the exclusion of anything to do with costing from hospital accounting.

The terms "subjective" and "objective" in costing parlance are quite clear in their meaning to accountants and administrators—but my article was addressed primarily to doctors, and they might be forgiven if they expected these words to have the meanings assigned to them in ordinary speech. Hence my brief explanation that, in costing practice, each operated as an extension of the other. My simple little diagram to illustrate this process was introduced solely for this purpose; your correspondent's attempt to read into this diagram a detailed scheme, as if a costing system were a huge grid of rows and columns in a literal sense, is surely unjustified; I cannot believe that he really thought I meant just that.

It is true that "to accent the objective classification of expenditure does amount to a fresh outlook"—but the *freshness* of this change is felt mainly by those trained in the subjectively orientated accounting systems. The idea was fresh to me, twenty years ago—but lay people do not suffer from the disadvantages of such a training, so there was no need for me to labour the point in an article addressed to doctors.

Your correspondent's grumble that (in my suggestion that statistical statements should be adapted to the various tiers of administration) I omitted to mention the individual hospital, is unfounded: I referred to the obvious fact that hospital management committees review the costs of running "the various separate clinics and hospitals within their group."

Possibly my warning against the misuse of costing systems was "platitudinous"—but maybe I shall be forgiven, for it was also "no doubt much needed." Just how much this warning may be needed in the future is problematical, but I may refer "Administrator" to one of the three reports on hospital costing now available, in which he will find that the detailed time-study of surgical operations is envisaged as part of an interesting research project. Is it impossible that this might lead some readers to suggest that, for example, a subtotal thyroidectomy should take x minutes? Can your correspondent not see that some enthusiastic technicians in time-and-motion study might write down as "unproductive time" that interval in which the surgeon is not visibly acting, but thinking?

It is precisely *because* I have seen the enthusiast in action that I warn my colleagues against this kind of "too-enthusiastic adoption of detailed schemes."

I assure "Administrator" that I normally use the right end of my microscope; but, if some costing enthusiasts had their way, I might find myself having to take a bus journey to another laboratory to visit the microscope installation, there centralised so that a shift system could be operated—"thus raising to a more satisfactory level the percentage usage of the instruments" (I quote from a possible future Costing Report to the Minister).

To be serious, I repeat my plea that doctors and administrators should discuss the whole problem. No-one likes being administered, and no-one likes being ill; but administrators and doctors are often quite pleasant people. Both have problems—and opportunities—of avoiding the most irritating features of costing systems in the context of hospital work.

Let it be recognised that there is a likelihood that doctors may be a little on the defensive (or just not interested) in relation to costing schemes; and that administrators also may be a little sensitive when alterations in accounting procedures are contemplated. If this is the situation, then surely informed discussion will clear the air?

London, N.W.3. A. F. MOHUN.

SIR,—Mr. R. S. Murley (June 6) takes me to task for suggesting that low bed-occupancy rates imply inadequate use of hospital beds. I can best reply by quoting the experience of our hospital in recent years. Pressure on our beds had greatly increased, as the number of new outpatients referred to us had gone up by 20% a year. Nevertheless, without an increase in beds, we have done much towards dealing with the resulting increased demand for admissions. This has been done by raising the bed-occupancy rate and by reducing the average length of stay, *without any apparent loss of medical efficiency.* The following figures are quoted from the last available annual report (1951):

—	1949	1950	1951
Beds			
Complement at end of year ..	853	862	862
Daily average number of beds occupied	769	806	807
Percentage of available beds occupied	90·15	93·5	93·6
Discharges and deaths during the year	13,684	14,431	15,639
Average length of stay (excluding confinements, pulmonary tuberculosis, mental observation, and chronic sick) in days	18	17·05	15·85
Outpatients			
New patients (excluding casualty)	24,355	30,254	34,089

The changes in the indices may not appear impressive until it is appreciated that, with virtually the same number of beds, we have admitted a further 2000 patients a year—an increase of 15%, and equivalent to building a 100-bed extension. This achievement has been made possible by having a whole-time admission officer and a geriatric physician, by the careful planning of elective that the discovery of disability has possibly justified the cost of the examinations Whether these examinations could equally well be conducted by health visitors is another question

FUTURE ORGANISATION

In spite of some reservations about *routine examinations*, we do not share the doubts which have recently been expressed about the present usefulness of the clinic services What seems to us to be in question is not their value, but the efficiency of their organisation under the National Health Service Act

Before considering their future organisation it may be helpful to state three principles which would probably be generally acceptable.

(1) It is unnecessarily expensive for doctors to undertake duties which can equally well be performed by health visitors

(2) It is undesirable to divide between more than one doctor personal services which are well within the competence of a single doctor, or could be made so with slight modifications in his training or experience

(3) The supervision and treatment of children can be conducted more satisfactorily from a local-authority clinic or health centre than from a general practitioner's surgery

There is little in the advisory work of the clinic doctor which could not equally well be done by the health visitor Indeed the conditions for which medical advice was given (weaning, maintenance of breast-feeding, complementary feeding, &c) are those with which the health visitor has been trained to deal, and undoubtedly would deal if no doctor were present During the late war many clinics were run by health visitors without medical assistance It therefore seems reasonable to suggest that if alternative arrangements were made for the strictly medical functions of the clinic (treatment, referral and possibly routine examination), the other services (food distribution, regular weighing, and advice) could be conducted by health visitors without a doctor More emphasis could profitably be placed on the domiciliary work of health visitors, since there is still force in the criticism that the clinic is most regularly attended by mothers least in need of advice

The fact that the preventive and curative personal services are still divided between local authority medical officers and general practitioners is well known What is not generally appreciated is that clinic doctors give a substantial amount of treatment of 1096 children seen in Birmingham and Coseley 279 (25%) were treated at the clinics and 130 (12%) were referred elsewhere

The *principle that all general medical services* for children should be undertaken by the same doctor seems unexceptionable Moncrieff (1950) has written of the infant-welfare service "Its medical officers should logically be the family doctors who will be carrying out the work in the homes as well as at the infant welfare centres" Moreover it is easy to see that such a proposal could be realised at health centres Parsons (1947) looked forward to the time when "among a group of medical practitioners working at a health centre, there will be *some who are keen on work* amongst children, whereas there will be others who will be glad to hand over their care of the children, both in health and disease, to their colleagues The former in time will come to be regarded as the pædiatricians of the centre, and specialize more and more in this work" The question is whether all progress in this direction must wait upon the appearance of health centres

It seems to us that it need not Some general practitioners already do their antenatal and postnatal work at local authority clinics, and there is no obvious reason why at the same sessions they should not provide a comprehensive service for children on their lists These services might include medical consultation, treatment, immunisation, vaccination, such routine inspection as is considered necessary the extent that the services go beyond those he has hitherto provided, the general practitioner should receive additional payment Probably the most satisfactory means of arranging this within the present administrative framework would be to pay an increased capitation fee for children to practitioners prepared work at the clinics and to provide a full child health service It has been objected that few of them are at present equipped to give such a service, and certainly the present inquiry suggests that many mothers are dissatisfied with the service offered by general practitioners to their children But we must begin somewhere, and unless circumstances are created which provide general practitioners with the incentive and opportunity to do this work, it seems unlikely that their training and experience will progress very rapidly

It would be wrong to end this discussion without some reference to the future of the clinic medical officers For many years they have provided a service for a substantial section of the child population when it was available from no other quarter Some of them have thus acquired from experience, if not from formal postgraduate training, a considerable knowledge of children's diseases If their responsibilities are eventually to be taken over by general practitioners, it seems reasonable to propose that the more experienced clinic medical officers should be given the opportunity to find a place within the new class of general practitioner pædiatrician which will in time emerge Such an arrangement would help to ensure a continuity of service, and the unification of the preventive and curative personal services would finally remove an anomaly which owes its origin to circumstances which no longer exist

Summary

An examination of the work done at child welfare *clinics in Birmingham* shows that on the average 101 mothers attended each session, of whom 51 bought food at the branch food office, and 50 entered the clinic proper Of the 50 who entered the clinic, 7 attended without the child to obtain priority foods, 43 attended with the child, of whom 20 came to have it weighed, 8 to get specific advice, and 15 to obtain priority foods Of the 15 who came *for foods, 11 wished also to have* the child weighed, and 2 *to have advice about its* management

Of the 43 children, 17 were referred by health visitors to the clinic doctor, whose work consisted of routine examination of the child, followed, when necessary, by reassurance of the mother (4), advice about feeding management, or priorities (6), treatment (4), and referral (3) Similar results were obtained in Coseley, an urban district with a population of 34,414

It is suggested that the advisory work of the clinic medical officer might now be taken over by the health visitor, and his medical duties (treatment, referral, and *routine examinations) by general practitioners* This could be done, in the absence of health centres, by paying an increased capitation fee for children on the lists of general practitioners prepared to provide a full child health service from local authority clinics The more experienced clinic medical officers might then be given the opportunity to find a place within the new class of general practitioner pædiatrician which would *in time emerge*

For permission to conduct this inquiry we are indebted to Dr Matthew Burn and the Public Health Committee in Birmingham and to Dr G Ramage in Staffordshire The work in the Birmingham child welfare clinics was greatly assisted by the generous coöperation of Dr Jean Mackintosh

admissions by all members of the senior staff, by the excellent coöperation of the pathological and X-ray departments in the rapid introduction of new methods of diagnosis and in the control of treatment, and because the level of medical and nursing staffing was adequate.

The bed-occupancy rates reported in the Ministry's Annual Costing Returns, to which I referred in my previous letter, reveal extraordinary discrepancies between hospitals of a similar type doing the same class *of work. Even more striking* are the variations in the average length of stay (as yet unpublished). Taking five large general hospitals, in Greater London, chosen only for their similarity of function, the average length of stay *per patient* is recorded as 27, 25, 19, 19, 16 days, with bed-occupancy rates of 77·0, 89·6, 90·8, 82·0, 83·2 respectively.

I am fully prepared to admit that there may be important fallacies in relation to many of these mass hospital statistics. There may be a difference between the working total number of beds and the figures recorded by the hospital administrators; beds long since taken down may still appear in the administrative total from which the bed-occupancy rate may be calculated. The association of chronic or convalescent units must be taken into account. The lowest average length of stay for a large general hospital in this country is only 12 days, but this particular hospital has a big convalescent unit closely associated with it. It is important to distinguish between optimum and bare minimum length of stay; a shorter length of stay for a particular disease does not necessarily imply better treatment. While appreciating these fallacies, from my own personal observations I suspect that the wide variations in these indices mainly correlate with the numerical adequacy of the medical and nursing staff, and if this is so, it is important that it should be clearly and officially recognised.

My point, which I maintain is a reasonable one, is that in spite of possible *fallacies*, the wide *variations* in these indices, together with our own experience, suggest that some hospitals are using their available beds inadequately and that this is an extravagance which *the nation cannot afford. Hospitals are a particularly* expensive social service, and it is reasonable that every effort should be made to ensure that the maximum use is made of their facilities—particularly of beds related to the expensive ancillary departments.

Lay members of medical committees are perfectly right in raising queries about bed-occupancy and similar indices of hospital efficiency and in seeking assurance that the problem is being studied. However, they should realise that the subject is a complex one which can be dealt with adequately only by senior medical and nursing staff and the administrators—who must be prepared to recognise the existence of a problem and study its solution. Once any problem is defined, one is already half-way towards a solution. Simple measures may help enormously. In one large Midland hospital it was customary to discharge patients in the afternoon, and by a local nursing tradition the beds were not filled until the following day. By discharging patients in the morning and filling the beds the same day (except those for duty admissions), the hospital made some 6000 extra bed-days available each year—sufficient for the admission of another 300 patients.

Mr. Murley is quite wrong, I believe, in suggesting that an increased turnover almost inevitably means a fall in the percentage bed-occupancy. Indeed the reverse is the truth.

I wish to underline my previous statement that a general community hospital should have at least a 90% bed-occupancy and that 93% is perfectly feasible. My private opinion is that even this figure could be increased by further reorganisation; and indeed last month we recorded a 96% bed-occupancy. The wide application of our experience should result in an appreciable fall in waiting-lists. Mr. Murley says tha "unoccupied hospital beds are surely less of a extravagance than an unnecessarily occupied one." My point is that if there are these unoccupied beds, a suggested by the Hospital Returns and confirmed b Mr. Murley himself, they should be mobilised to dea with the national waiting-list, which stands at approximately 500,000. There is a strong case for every hospita medical advisory committee to review carefully its ow experience. I anticipate that the King's Fund repo will make many practical suggestions which could b implemented.

Central Middlesex Hospital,

London, N.W.10.

F. AVERY JONES.

INJURIES OF SPINAL CORD

SIR,—In your annotation last week you refer experimental injuries produced in rats and dogs. Th you go on to state that "the direct trauma used these animal experiments is not really comparable wi the indirect trauma which commonly causes spi injuries in man." Of course it is not, nor is it like that early incision of the pia and posterior myelecto in cases of human spinal injuries will produce go results. I maintain that such experiments, apart fro causing needless suffering especially to dogs, is a she waste of time. My confirmed belief is that on the wh animal experimentation has become an obsession and not furthering our knowledge of practical medicine surgery.

Edinburgh.

JAMES BURNET.

PREVENTION OF POSTOPERATIVE CHEST COMPLICATIONS

SIR,—We would like to draw attention to a m quotation in Dr. Davidson's article last week.

According to this article, a description of the use benzocaine and urethane for the treatment of pain stumps was given by Ritchie Russell and Spalding 1950. There is, however, no reference to benzocai urethane in the article referred to,[1] which deals wi percussion therapy for painful stumps. The descripti of the use. and the principle underlying the mode action, of benzocaine urethane was published by Ko and Vitali in August, 1950,[2] following the article Ritchie Russell and Spalding.

As to the rationale of Dr. Davidson's method, it not clear why benzocaine should be first made up in o and injected separately before the urethane is introduc *Injected oil is not always well tolerated*; and there do not seem to be a necessity for introducing it, sinc benzocaine in a proportion of 2% is well soluble in a aqueous urethane solution and it can therefore b injected as such a solution. The effect is the same—i.e the formation of microcrystalline deposits of benzocai in the tissues. Benzocaine, being insoluble in water, almost immediately precipitated by the watery tiss fluids, and the urethane is absorbed.

In connection with the increasing interest in th problem of local anæsthetics of long action it migh be worth mentioning a few data. *Benzocaine* in urethar was first introduced, and its mode of action described, b *Rappaport*[3] *in 1946, and its clinical application* reporte by Spiro.[4] Following their publication a 2% solutio of benzocaine in urethane was manufactured by Messr Zori, of Tel Aviv, under the trade name of 'Prolonga Benzocaine.' Further reports were published by Drosel Rachet et al.,[5] Hirsch in Scandinavia, and others.

tioners has already been mentioned in this column[1] Of course no one would expect acknowledgment in all cases The man who sends a patient straight to hospital with a scrawl "Buzzing in the pants ? piles" cannot expect to be immortalised when his colleagues Professor Katz and Mr Kittenz later publish An Unusual Case of a Mechanical Mouse in the Rectum But the good general practitioner who refers his patient to a hospital consultant as an act of consultation after doing his best, supplies an adequate history, and is responsible for the patient's pre- and post- hospital care, is surely entitled to some credit Moreover, such an acknowledgment might help to impress on hospital staffs that they deal with people, not cases, whose visit to hospital may be but an interlude in the family doctor's continuing and life-long effort to maintain their health

No doubt a dignified rebuke on college notepaper will do the trick

12TH NIGHT

The tumult and the shouting dies,
The devilled bones have been consumed,
All pudding spent, the cold mince pies,
With cakes and ale and sugar plums,
Have been engulfed and rest entombed
Uneasy in distended tums
Nothing remains of nuts but shells,
Nothing of tangerines but pips
For supper there is nothing else
But cœlacanth and chips

* * *

Crump! That was the door of the doctor's car I stopped smoking, switched off the wireless, and assumed the air of one fighting for life Relaxing afterwards, I recalled an earlier illness The purple warning then was the brisk plink-plonk of a pony, and the red was a round brass bell dangling from its neck The trap and its accoutrements were spotless Doctor and coachman were alike as two peas—silk hat, frock coat, moustaches and all I remember the tonsilloscopy by teaspoon and the rattle of starched cuffs when the thermometer was shaken

The bedroom wallpaper was an endless replication of roses, and a glass globe encased a fish-tail burner A jug stood in its bowl in front of heavy lace curtains By night I watched the flickering firelight on the ceiling By day I was visited by ladies in huge hats transfixed by pins and further secured by veils discreetly lifted to admit fancy cakes They sang *Sunshine and Butterflies* and *Little Grey Home in the West* But what are the wild waves saying today? They are saying *Moon over Madagascar*, a fantasia for electric organ We are back in England now!

* * *

A friend of ours who dabbles in psychiatry recently purchased a young horse, partly in order that his waistline could be held to the limits of his present wardrobe, and partly so that his children could add equitation to their other numerous accomplishments The animal has taken charge of the household very satisfactorily, and apart from a tendency to request admission to the warmth of the kitchen fire at inopportune moments, has settled in well For some time now our friend has been superintending the erection of a covered shelter of concrete blocks to protect the horse from the inclemencies of the English winter, and in this charitable work he has been assisted by a youth who has an aptitude for the compounding of concrete but little talent for conversation On several occasions our friend has observed the youth and the horse eyeing each other with undisguised apprehension, and finally he taxed his helper with an un-English lack of sympathy with the great family of *Equidæ* The unnatural boy readily agreed "You see," he explained, "my mother was frightened by a horse before I was born"

Letters to the Editor

FROM TEACHING TO LEARNING

SIR,—Your leading article of Dec 27, d of the activities of the Commonwealth Fund in th of university medical education in the United prompts me to record some impressions I received recent visit The Fund invited me, as a former f of the foundation, to visit some centres where in medical education were under way Perhaps the enterprising is that taking place at Western Re University School of Medicine in Cleveland, Ohio I was fortunately able to attend the opening exer of the first year of the new curriculum

Eighty new students were enrolled The first days ("orientation period") were devoted to intro the students to the school and faculty, to the curriculum and modern medicine On the first day were the usual University Convocation, registrat physical examination, and photographing, and int ductory remarks by the dean of the faculty of medic On the morning of the second day, in the college amp theatre, the associate dean, a physician, described t *historical background of medicine*, the evolution of med education, the history of the Western Reserve Univers Medical School and its administrative organisati relation to hospitals, and finances This was informati explanatory, and put over in an able and pleas manner It was the first step As one doctor said to afterwards "Hell, it took me years to see that" In t afternoon the *new programme of medical education* described in more detail by a physician, a biochemi pathologist, and a surgeon Reasons, difficulties, an plans, and procedures were discussed Then an anatom talked of *the examination system* as a part of educati and the session finished with a discussion by a profe of preventive medicine on the *evaluation of medi education*

On the second morning there was first a discus by the professors of anatomy, pathology, and mic biology on the *importance of the basic sciences* (anato physiology, biochemistry, microbiology) in relation research, medical progress, and education The story diabetes was described The growth of our knowledge respiration, vitamin K, and immunology were used *illustrate the theme* Then followed a description, by t associate dean, of the *modern organisation of medi care* community agencies, hospital team work, a the rôle of the family physician (The term "gene practitioner" was not used)

In the afternoon the meeting-place was the univer hospital amphitheatre Here the associate dean, t professor of preventive medicine, and other member the staff cooperated in the *presentation of three patie*

The first patient told his story with the encouragement a assistance of one of the staff He had recently had an opera for mitral stenosis He described the vague symptoms rheumatism in childhood, the apparent cure, his surpris being rejected by an army board in 1941, his efforts at tr to find out what was wrong, the indifferent attitude of doctors and employers, the sympathy from a factory doc the endeavour of one firm to fit him in, the effect of worry a lack of money on the happiness of his home and sudde the tragedy of a cerebral embolism He recovered difficulties in earning his living, then symptoms of he failure, and finally unemployment and debt His state arrival in hospital, his attitude, physical capacity, sympto and signs were described and illustrated, and finally the g result achieved by dilatation of his mitral orifice was il trated He was back at work, paying his way, and ab care for his family All this was brought out in a simple a telling manner There were poignant moments and co ones too

The second case was of a young lady intern who contracted poliomyelitis while on hospital duty From

JUNIOR HOSPITAL STAFFING

SIR,—The article by Dr. Forrester in your issue of June 13 is very interesting and stimulating: but it is, I think, misleading in its comparison of the incomes obtainable by the whole-time specialist and the general practitioner. Out of his £3000 the latter has to find a considerable sum for expenses, while the former does not need to supply even a stethoscope or a sheet of notepaper.

The glittering prizes of the specialist are admittedly now very rare, but on the other hand the early years are surely much better than in the old days even allowing for the changed value of money. But was it the financial side of the glittering prize which induced a young man to take up a specialist career?

Wirral.

K. COBBAN.

LOCALISED MUSCULAR ATROPHY IN DIABETES

SIR,—I was interested in the comments of Dr. Harris-Jones (May 30) and Dr. Robertson (June 13) on the tentative view expressed in my note on isolated muscular atrophy in diabetes. On photographic rather than bedside evidence we are unlikely to agree as to whether a muscular component was or was not present in the lesions described. It is noteworthy that relatively non-fatty regions—the jaw and thumb—were involved in one case. In the absence of surgical exploration (a hole cannot be subjected to biopsy) doubt must exist.

However, the existence of "space-vacating" lesions in diabetes unrelated, at least in site, to insulin injections is not in doubt, although apparently it is not commonly recognised. To accept such lesions, again in the absence of histological investigation, as ectopic insulin atrophy is not entirely helpful. An explanation becomes necessary for an insulin effect which is simultaneously both localised and yet quite remote from the site of injection.

Royal Northern Hospital,
London, N.7.

CEDRIC HIRSON.

TROUBLESOME TAPEWORMS

SIR,—The course of treatment for tapeworm recommended by Dr. Asher (May 23) lasts 4–5 days and has to be carried out in hospital. Whilst serving with the R.A.M.C. at the 43rd General Hospital, I introduced the following simple treatment:

> The patient is admitted to hospital at lunch-time and is given a light meal. At 3 P.M. 2 teaspoons of magnesium sulphate are given as a purge. At 7 P.M. the patient gets for supper chopped herring with onions, 1 piece of toast, and a cup of tea without milk. At 6 A.M. *next morning* the patient is given 0·25 mg. of atropine, and at 7 A.M. a duodenal tube is introduced into the stomach. Every 10 minutes the tube should be advanced about 2 cm. until by aspiration with a syringe it is confirmed that it has passed into the duodenum. Now, 8–10 ml. of extract. filicis in 20 ml. liquid paraffin as an emulsion is passed through the tube into the duodenum. Usually at about 10 A.M. the complete worm is passed. If it is not passed by then a dose of magnesium sulphate should be given, followed 2–3 hours later by a high enema with fol. sennæ.

This treatment is completed in less than 24 hours and can be carried out in hospital or at home. I do not remember the number of cases we treated in this way, but it was quite considerable. There was never a failure.

Petah-Tiqvah, Israel.

E. FRANKL.

BREAD

SIR,—May I congratulate you on your leader last week, as well as on your able review of the controversy over flour improvers (March 21)?

Bread is the staple food of the population of Great Britain, and no economic change is likely to alter that. The quality of the national diet, based on this staple, itself contributes largely to the health, or morbidity, of our population. Experience shows that a diet based on whole wheat flour has kept other peoples relatively free from disease, and experiment has shown that diets of the same specification have also kept rats in health (R. McCarrison). Again, at the Rowett Institute near Aberdeen it has been demonstrated that not only deficiencies in the B group of vitamins but also inbalance of that group affects growth. The case for first-quality bread rests therefore not only on intuitive understanding but also on such experimental biological evidence as is available.

In his Sanderson-Wells lecture the arguments which Professor Dodds brings to the "brown versus white bread controversy" rest not on biological or medical experiment but on history, economics, and politics. What you call "economic and commercial convenience" stems no doubt from the vast capital investments in the milling and baking trades. It is in the interest of these investments that the present customs of their trades be maintained. Enlightened professional and public opinion is uneasy that the bread policy of the nation should be so largely governed by the investment policy of the past. Does this policy contribute to the high national morbidity? Let us say that we do not know, and then the best opinion will demand that we use every resource to find out.

It was disturbing to find Professor Dodds, with the secretary of the Medical Research Council in the chair, asking "who is going to do this work?" and opining that "the charge, surely, should not fall on public funds." If a question which touches the health of the whole population should not be a charge on public funds, and if other research endowment cannot finance such inquiries, the public must question the whole structure and administration of the moneys on which research depends. If those who have a virtual monopoly of the means cannot "do the work," then reform—which many of us believe is overdue—is surely called for.

With great respect, it seems to me a pity that Professor Dodds's review of the problem of chemicals and food should contain so little evidence of a scientific kind.

East Suffolk and Ipswich Hospital,
Ipswich.

K. E. BARLOW.

SIR,—May I congratulate you on your fiery and courageous leader last week, taking up the cudgels laid down by your illustrious predecessor Thomas Wakley a hundred years ago. It ought to be brought home to the public that the addition of the arbitrarily chosen "token" nutrients (aneurine, nicotinic acid, and iron) to white flour still leaves it with a lower (probably much lower) nutritional value than the 80%-extraction National flour.

While I agree with Professor Dodds about the importance of modern food technology, as a doctor I find it disturbing to see the chemical manipulation of food considered on the same level as technical advances in heating, housing, or transport. Have we to put up with agene and other "improvers" on a national scale only because the small baker in this country has been replaced by big-scale "plant bakeries"?

PERFORATION OF COLON AFTER BARIUM ENEMA

Sir,—The two interesting case reports of accidental injection of barium sulphate into the peritoneal cavity [1] [2] stimulate me to offer a further case-report

A man, aged 62, was admitted to the West London Hospital on Oct 25, 1952, with complete intestinal obstruction The pattern of the distension suggested colonic obstruction with a possibility of volvulus of the sigmoid colon I therefore did a sigmoidoscopic examination, using the standard Yeoman instrument with the patient in the knee chest position No resistance was encountered, nor did he complain of more than mild discomfort No lesion was seen up to 8 in, and the instrument was removed

In order to locate the site of obstruction, radiography with a barium enema was arranged No sooner had a few ounces of the fluid been run into the rectum than the patient became pale, and sweated and complained of abdominal pain The examination was therefore stopped, no radiographs having been taken

Laparotomy was performed the same evening On opening the peritoneum it was found that it contained a considerable quantity of milky fluid, and that all the intestines, mesentery, and omentum were sugared with barium A ring carcinoma of the splenic flexure was found to be the cause of the obstruction, and the site of the perforation was a linear tear 1 in long on the antimesenteric border of the sigmoid colon, far below the growth, and about opposite the promontory of the sacrum

The perforation was sutured and a Senn Kader cæcostomy performed The patient's recovery was complicated by peritonitis and a very irregular pulse, but he stood very well a resection and end to end anastomosis of the splenic flexure three weeks later, and has made a good recovery

This case closely resembles one reported by Isaacs [3]

General Infirmary,
Leeds

LIGATION OF THE POPLITEAL VEIN FOR THE GRAVITATIONAL SYNDROME

Sir,—Despite the somewhat guarded wording of the conclusions and summary to his paper last week, Mr Moore has none the less conveyed the impression that ligation of the popliteal vein is a procedure of some value in the treatment of gravitational leg ulcers

I would suggest that the facts recorded in his paper warrant no such conclusion He admits that in his experience popliteal vein interruption alone has generally not caused leg ulcers to heal He has therefore combined ligation with a period of bed rest and skin grafting and thereby completely confused the therapeutic issue It is of course well known that leg ulcers, whatever their cause, can almost invariably be induced to heal by strict bed rest and grafting alone without any interference with the veins The only way, therefore, in which the benefits of popliteal vein ligation might be revealed in Mr Moore's cases submitted to this combined treatment would be by a significantly lower incidence of recurrence of ulceration after discharge from hospital We are told that 7 of his 11 patients showed no signs of recurrence for periods from 9 months to 3 years I do not consider that these results are very different from what might be obtained after bed rest and grafting alone especially if the patients were careful to support the leg by an elastic stocking or bandage as apparently did most of Mr Moore's cases

My own experience of interruption of the deep venous system for leg ulceration due to old thrombosis or apparent valvular incompetence of the deep le has been confined to superficial femoral vein li but the principle of this operation and that of l of the popliteal vein is the same, and the results presumably also be similar I have now done 26 of operations, and, so that these patients might b up and about, the ligation was done in the outpa department, or was followed by at most 36–48 of hospitalisation Subsequently the patients att the varicose vein clinic for local treatment with U paste or elastic adhesive bandage It was thus pos compare their progress with that of other similar c treated only by bandaging There were variati usually quite unpredictable—in the rate of heal individual ulcers in both groups, but it could not claimed that in general the surgically treated g healed any more rapidly than the other, the time taken for complete healing was 9–10 month cases were particularly instructive, because they h ulcers on both legs and superficial femoral vein ligat was practised on one side only in each case, the oppo side serving as a control There was no obvious dif ence in the rate of healing in the two legs in ea case

These experiences have led me to abandon interrupti of the deep venous system in the treatment of leg ulcers

REPRESENTATION OF WHOLE-TIME SPECIALISTS

Sir,—On Dec 19 a deputation of representatives of t Association of Whole time Salaried Specialists met t staff side of Committee B of the Medical Whitley Counc and at that meeting matters affecting whole time offic in the National Health Service, including the questi of their representation on the staff side of Committee B were discussed [1]

In view of the well-known dissatisfaction in the min of whole time officers regarding the disparities whi have existed and still exist in their terms and conditio of service, as has been emphasised recently by mu correspondence in your columns, I should like to gi a brief résumé of the points which were put forward b our deputation to the staff side of Whitley Committee on behalf of whole-time consultants The following ar the particular matters to which we referred

1 The difference in remuneration between the two clas of consultants (whole time and part time) is $1^1/_2$ sessions or, expressed in cash on the basis of the top grade of salar £375 per annum

2 To offset this difference of £375 per annum, the part ti consultant has the following

(a) Private practice
(b) Payment for domiciliary visiting up to £840 per annum
(c) The right to claim mileage allowance from his home t consulting room
(d) The ability to claim, without difficulty, income ta relief for many items for which the whole time consultant cannot claim, such as subscriptions to learned societies, purchase of medical books and periodicals expenses of attendance at congresses and clinica meetings, and car and telephone expenses

3 The importance of car allowances for whole time consultants was stressed It was pointed out that a car i essential as all whole time consultants must be quickly available for emergency calls and domiciliary visits if agreed to be undertaken The same applies to telephone rentals At the request of the staff side, concrete instances were giv of the unsatisfactory mileage arrangements and the anomalies that arise out of them

4 It was pointed out that the Spens Report on Consultants (para 17, 6) in our view recommended that all specialists should be on an equal basis in regard to payment for domiciliary visits, and we asked for reconsideration of th interpretation of this paragraph

It has occasionally been argued that the digestibility of bread prepared from high-extraction flour is inferior to that of white bread. I may have been particularly fortunate with my dyspeptic patients, but I hardly remember anyone suffering from peptic ulcer who could not enjoy whole-meal bread after proper instruction how to take it.

London, W.1. Z. A. LEITNER.

RELIEF OF MENTAL HOSPITALS

SIR,—May I suggest that, to relieve our overcrowded mental hospitals, every suitable general hospital should set aside two small wards each of, say, 10 beds for male and female patients with affective disorders whose condition does not necessitate treatment in a mental hospital. Patients with nervous disorders have as much right to be treated in general hospitals as maternity, surgical, or medical cases. A trained registrar could be put in charge of these psychiatric units and the work supervised by a visiting consultant. Minor psychotherapy could be carried out there, and refractory cases could be referred to a mental hospital.

The advantages of such a measure would not be limited to the relief of overcrowding. Patients with affective disorders are likelier to respond to treatment in a general hospital than in a mental hospital, where for the time being neurotic patients have to be mixed with chronic incurable cases. Moreover neurotic patients would escape possible stigma in the public's view for having been treated as "mental patients." Lastly, the general hospitals themselves would benefit; for house-officers would be able to familiarise themselves with the managemental of mental patients. The arrangement would bridge the artificial gap dividing those who treat physical disorders from those who treat mental disorders.

Powick Hospital,
Worcester. J. W. MULLNER.

THE ILLEGIBLE CANDIDATE

SIR,—Everyone will agree with Mr. E. W. Playfair (June 13) that bad handwriting is to be condemned. Everyone will also congratulate him on having learnt, at the age of 22, to write well after a few hours' lessons, spread over a few days, and will also admire his signature. My experience is, unfortunately, very different. When I was 21, I was told by Dr. Walter Morley Fletcher that, although he could read *my* writing, I *must try* to improve it. I spent the Christmas vacation going to Clark's College, Chancery Lane, three or four days each week, and was taught to write in the way the girls who were sitting for the Post Office examination wrote. I also practised hard for the next two years, and the legibility of my handwriting was greatly improved: but it was very difficult to maintain it in the stress of examinations and in writing notes at hospital on my knee. Now that I am old, I have writer's cramp if I do much writing. I can still write legibly if it is necessary, but it is a slow and painful process. My usual writing is bad.

The ability to write well varies as much as the ability to play games. Everyone seems to expect a boy or girl to be able to write well without any difficulty, though no-one expects people to be equally good at games. For instance, some people, having great ability, learn to play golf very easily, and soon reach a "handicap" of scratch; some after a few lessons likewise improve easily and reach a low "handicap"; others, like myself, after many lessons and much hard practice attain a moderate "handicap." Others, no matter how many lessons they have, or how much they practise, never attain a "handicap," and give up golf in disgust, and find some other means of taking exercise or spending their time. Unfortunately, people who cannot improve their handwriting still have to go on writing, and so distress the recipients of their letters especially when they
do not type their names under their signature
possible that if I had been taught by another
I might have written better; but I am afraid I
never have been a good writer. Similarly I
think any teaching would have made me a scratch

I have never consciously marked down a ca
either for his handwriting or his bad English, s
may make a very good doctor in spite of these dra
I once failed to read an examination paper for
degree because the candidate wrote his words a
above as below the lines, and his paper looked
series of small waves. I managed to decipher en
realise that he was talking sense, and my co-ex
and those who read his other paper agreed to gi
half marks, and let his fate be decided by the
and vivas. He passed very easily, and we request
he be told that his handwriting was very bad, a
he ought to try to improve it.

I hope *these* confessions of a notoriously bad
will support Sir John Conybeare's plea that bad
should not be penalised, though they should be
in the interests of the pharmacists and of their fri
write more legibly.

London, W.1.

GEORGE GR

SIR,—As an examiner, I have never been
worried by the bad manners of the illegible candida
I have often been surprised by his stupidity. *Ha*
by an illegible script, I feel that I ought to deduct
but I never do—consciously, at least. Bad handw
stamps a candidate as lacking in ordinary n
serious failing in any student who hopes to qualif
doctor. However, until examiners as a whole ag
this, and warn candidates in advance that illeg
will be to their disadvantage, it is not fair for indi
examiners here and there to exact penalties for bad
writing (let alone crude spelling, or the *inability* to
a clear English sentence).

The illegible candidate is a fool to treat his
examiner so. Let him envisage what happens t
scripts.

They arrive in two or three large parcels at the home
examiner—who is almost without exception a kindly,
pathetic human being. They make a rather bulky-l
pile, to be marked in time, and (if there are many whi
difficult to read) maybe against time. They probably r
on his desk until he gets home at the end of a day's
has his dinner, and settles into an armchair in front
fire. He starts with a sense of interested and, indeed, h
anticipation. Most candidates will not misunderstan
however, when I add, with great respect, that exami
scripts, in bulk, are not unduly inspiring reading.
examiner makes full allowance for this; but if by cha
comes upon a set of answers well and soundly set out in
handwriting and readable English, he warms to the cand
perhaps even a little excessively because of the contr
the "general form."

Sooner or later comes the inevitable unreadable
writing. The examiner stumbles *on for a sentence or tw*
then comes across a word which he cannot recognise
turns the page through various angles in the effort to de
it; he re-reads the previous sentences to see if they wil
him to the sense of the word; or he *may* even ask his
opinion (if, indeed, she has not already gone to bed). E
time it has been deciphered, he has probably forgotten
the candidate has said earlier. "Blast this chap," he m
good-humouredly, "why wasn't he taught to write pr
at school?" But he stumbles again, and again, an
again, loses the thread of the argument, re-reads, and
even have to make notes on paper, to ensure that he will
the candidate's meaning, and to assess whether he has co
the essentials of any proper answer to the question.
examiner, poor chap, has taken three or four times as lo
go through this paper as through a normal *one*, wit
altogether needless expenditure of energy. If he is as adm
as some of my friends who *have contributed to* this discu

MORE DOCTORS OR MORE ANCILLARIES?

SIR,—Your excellent leading article last week raises one of the most important problems for the future of medical practice under the N H S in this country

Since, as you rightly assume, it is all-important that we shall maintain the standards of medical training, it seems to be inevitable that more and more of the techniques of medicine and surgery must gradually be decentralised on to the ancillary medical professions This is probably a legitimate form of "dilution"

The central problem at present inherent in this tendency is, as you suggest, to determine at this stage whether these professions shall be regarded for this purpose as "daughter" or "sister" professions of medicine It was presumably in recognition of the need to face this problem that the Ministry of Health in 1950 set up the eight Cope Committees Important majority and minority reports were published embodying their findings and recommendations about eighteen months ago Since then little or nothing further has been heard of the matter

This is a very unsettling situation both for us and also for the members of the ancillary professions It has led to some members of the latter being encouraged by this interregnum to plan for autonomous status within the N H S

In view of your statement that "the proper use of ancillaries is a major issue on which doctors ought to be forming a considered opinion," it would seem desirable that the authorities should proceed to the next step, which is presumably to draft a Bill based upon the findings of the Cope report and submit it for further discussion in Parliament

London W 1 W S C COPEMAN

CLINICAL STUDY OF ADRENOCHROME

SIR,—The interesting letter by Dr Srinivasan (Oct 4) prompts us to make a few comments

Our experiments in the same field led us to consider the action of the products of oxidation of adrenaline upon the adrenal cortex of rats and men

We found that intraperitoneal injection of adrenochrome, trihydroxy N methylindol (T H N I), and *semicarbazone* of adrenochrome (adrenoxyl), in doses of 100 µg per 100 g body-weight to intact male rats, produced biochemical and hæmatological signs of adrenal hyperactivity [1]—i e, adrenal ascorbic acid depletion, decrease of adrenal cholesterol, and a fall in the level of circulating eosinophils The action of 100 µg of each of these substances is, however, less than that of *l*-adrenaline in doses of 20 µg per 100 g body-weight The semicarbazide chlorhydrate and the semicarbazone of glucose are inactive in the same doses Thus, adrenal stimulation by adrenoxyl does not seem to depend on the semicarbazone radical, as was suggested by Gabe and Parrot [2]

As adrenoxyl does not enhance the effects of adrenaline, then the stimulation of the adrenal cortex by the doses used in our experiments is not due to this sympathicommimetic hormone Moreover, the action of adrenaline does not depend on the oxidation products because adrenaline is active in a smaller dose

The urinary excretion of reducing steroids and 17-ketosteroids was estimated in patients who had had an intravenous injection of 1 mg of adrenochrome twice daily for five to ten days, and in other patients who had had 9 mg of adrenoxyl (in 3 doses) every twenty-four hours for three successive days No significant change was found in the urinary excretion of the steroids, though there was a significant and regular decrease in the circulating eosinophils This discrepancy between animal and clinical experiments may be due to too small a dose in man, and further investigation may decide this point

But there is no disagreement between animal clinical experiments with salicylates in large do our results with salicylates [3, 4] suggest that it is s which is in fact the "poor man's cortisone"

CHRONIC OTITIS MEDIA

SIR,—I must have expressed myself badly at Royal Society of Medicine for your reporter to h misinterpreted me (Dec 20, p 1208) I do not beli "failure of pneumatisation" of the mastoid bone, b radiography shows the presence of diploitic cells a apophysis develops Somehow some of these com communicate with the antrum, forming the pneu cells Then a non-suppurative otitis media from the respiratory tract results in a cond periostitis under the mucosa which is also the inter periosteum of these cavities According to the nat and severity of such inflammations the mastoid pro may be modified from the normal cellular type into t so called diploitic type or the sclerosed mastoid T must, I think, be the process that causes these anom

Evidence is hard to produce, but various bits may b pieced together First, there is the occasional unilat sclerosed mastoid Anatomical variations such as th cannot be called normal Nature does not build sy metrical bilateral structures in that way Then again otologist whose work was concerned almost entirely w the acute inflammations, as mine was, did not come acr any other than cellular mastoids under adult or l adolescent life Nor does he see them by radiograph It was in the '20s that this first taught us that t normal mastoid is a cellular structure, and that t patterns of the cells in the two sides, though not identic are similar one to another I have often confirm this by using the radiogram of the normal mastoid to t me how far I must go when operating on the disea side, finding, more than once, cells in the squama of t temporal bone of which there was no sign in the blurr photography of disease, or going downwards and bac wards or up into the area where posterior and midd fossæ of the base of the skull meet on their later aspects

Sometimes, but very rarely, one picks up eviden from isolated cases

About twenty four years ago the first mastoid X picture was taken at the North eastern Hospital, not decide whether a mastoid operation should be done bu study otitis media And there was the bad side "all blurre in distinction with the clearly outlined cells on the other and this within forty eight hours of the first symptom exploded the old hypothetical pathology of successive jump and in course of time the modern concept of inflammat of the middle ear cleft took its place

Twenty years later the boy became one of my last dre The old plate had been destroyed, but a new one showed th cells on the two sides with patterns similar—but not identic because the cells in the side that had been inflamed we smaller than those on the other, with thicker walls betw them

One other case I had A young lady of the W R N had been sent back from Algiers for operation, with t diagnosis of mastoiditis The depth of the meatus was acutely tender that I wondered whether she had ever had inflammation of the middle ear cleft at all or whether the co dition might not be an otitis externa kept up by the irrita drops that had been used And so a radiogram was tak and there was a cellular mastoid as clear as the stippling t one sometimes sees on the background of an engraving said to her "Have you ever had anything wrong with t other ear?" and she answered "Oh yes! I had it bad

FRANK STOREY CLIFF

M D Lond, M R C P

Dr Frank Cliff, who died at Blackpool on Dec 3 at the age of 46, was for many years physician to the Queen Victoria Hospital, Morecambe, and to the Royal Lancaster Infirmary where latterly he also had a clinic in dermatology

He was a native of the city of Lancaster and proud of his connection with the red rose He got his early education at the Lancaster Royal Grammar School where he proved himself a keen scholar, a sturdy rugby forward, and an imperturbable cricketer In 1924 he entered University College Hospital, London where he maintained his reputation for scholarship and sportsmanship He played rugby and cricket for his hospital, and he qualified in 1929 Within the next three years he also acquired the M B, M R C P, and M D

While Cliff was holding a house-appointment at U C H he was closely associated with Sir Archibald Gray, who gave him his first and lasting ambition to become a dermatologist His last house-appointment was in his native Lancaster where he was senior house-surgeon at the Royal Infirmary Later he joined a general practice as the physician in a large firm in Morecambe where for many years he did much of the specialised medicine, and in a short time he was universally recognised as giving a sound opinion on medical and dermatological cases

"With Frank Cliff's experience and qualifications" J McF writes, 'one would have expected him to specialise early, but he wanted to learn medicine the sure way During those years of achievement, he served a community which will always be grateful for his work Under the National Health Service he achieved his ambition to become a consultant dermatologist, but, while this was what he himself desired most of all, many of his colleagues thought that the gain of dermatology had been the loss of medicine He served a large and scattered area stretching from Barrow to Blackpool and including Kendal Lancaster, and Morecambe, and throughout this wide area he made many friends He will be sorely missed in Lonsdale, both north and south of the sands and with his wide experience and encyclopædic knowledge of two specialties he will be a hard man to follow and one whom it will be almost impossible to replace"

FRANCIS CARLTON OLIPHANT

M.B Melb, D C H

Dr F C Oliphant, assistant pathologist to the Dudley Road group of hospitals, Birmingham, died on Dec 27 at the age of 17

He qualified at Melbourne in 1933, and he had practised in Australia both in city hospitals and up country when he came to England before the late war After holding house-appointments at the Woolwich and District Hospital, and at Great Ormond Street, he took the D C H in 1941 During the war he served with the Royal Navy as a surgeon lieutenant in several theatres After the war he held pathological appointments at Cheltenham and Birmingham, and at the time of his death besides his appointment to the Dudley Road group of hospitals he was visiting pathologist to the Yardley Green Sanatorium and a member of the coroner's panel of pathologists

F E D G writes 'Oliphant had had almost 20 years of varied medical practice It was as a pathologist that I knew him, and it was abundantly clear that his work in pathology was greatly influenced by his wide clinical experience His appreciation of the basic values in medicine, his innate common sense, and his intuitive mistrust of charlatans made him an invaluable colleague As a person his approach was shy yet direct His sense of humour was highly developed—dry, and full-bodied like a fine sherry His knowledge of the classics was extensive, though he would rarely give evidence of its existence He had a wide knowledge and appreciation of good music, and considerable ability as a pianist He was an excellent raconteur and his stories spiced with shrewd reflections on men and their failings and occasionally embellished with those adjectives for which Australia is famed made him a delightful companion Modesty and a kind heart were his greatest virtues, and I never knew him to display a trace of malice He was admired greatly both by his clinical colleagues and by the technicians who worked under him His death will leave a gap in the lives of all who were happy to work with him"

The Health of London in 1951

he decline in the *number* of children who are being unised against diphtheria each year continues: in county of London, for example, 40,656 children were unised for the first time in 1951, compared with 389 in 1950, and 22,908 had boosting doses—over 0 less than in 1950. The county medical officer. J. A. Scott, in his report for 1951,[1] says that one son for the decline is the publicity given to exaggerated orts of cases of paralysis following inoculation in 49 and 1950. Moreover, the success of the immunisan campaign has taken away much of the parents' ead of diphtheria and led them into apathy. Dr. ott's department is seeking further means of convincing em of the seriousness of their omission. On the other nd, the total number of people vaccinated rose from ,583 in 1950 to 35,470 in 1951, and there were more an three times as many revaccinations. The smallpox idemic at Brighton in January, 1951, was reflected in substantial increase in the number of vaccinations in ondon at that time.

The general death-rate in London went up from 1·3 per 1000 population in 1950 to 12·6 in 1951. The rise attributed to more deaths from cancer, heart-disease, nd respiratory disease in a gradually ageing population. nd to the influenza epidemic. The increase in cancer of he lung shows no sign of stopping: during the last wenty years the mortality among London men has ultiplied three and a half times, and the rate for vomen is now two and a half times its 1931–33 level. Deaths due to diabetes declined steadily between 1939 nd 1947, but the rate has been going up again since hen, supporting "the impression that the previous lecline had been connected with the dietary stringency of the war and post-war years." There were 282 deaths rom motor-vehicle accidents in 1951—37 more than in 1950—and the report points out that each year there are more deaths from this cause than from poliomyelitis. The infant-mortality rate, at 25·4 per 1000 live births, was lower than ever before; and the neonatal rate of 17·3 was well below the average of 20·4 for the past ten years.

The report mentions some figures from the 1951 census. The population of the administrative county of London has fallen by just over 1,000,000 (24%) since 1931. The decrease has been greatest in the East London boroughs; and only Hampstead, Woolwich, and Lewisham have shown an increase. The main reasons for the change are "slum clearance, migration into outer London, change in the class of user of residential accommodation, and bomb damage."

Dr. Scott has also published some preliminary figures for London in 1952. The infant-mortality rate is provisionally given as 23 per 1000 live births, which would again be lower than ever before; and the suggested neonatal rate of 15·6 per 1000 live births would also be a record. The birth-rate continues to fall, as it has done since 1947, and the estimated figure for 1952 is 15·4 per 1000 population, compared with 20·9 in 1947 and 15·6 in 1951.

In England Now

A Running Commentary by Peripatetic Correspondents

OUR lecture room exemplifies the British ideal of the maximum of inaudibility with the minimum of ventilation. The seating is carefully designed so that the knees of the student become painfully and inextricably wedged against the sharp edge of the bench in front, while the spines of his scapulæ are assailed by the sharp edge of the bench behind. The occupants of the back benches, out of earshot and almost out of sight of authority, spend their time happily playing pontoon. In contrast, the seekers after truth in the first two rows either gaze soulfully at the lecturer's face, their lips moving silently to the rhythm of his discourse, or feverishly attempt to record in their notebooks every word and every significant cough or pause in the hope that it will come up in the exam.

In the middle rows between these two extremes is the great student body, vast, inchoate, and drowsy. When one of its legs goes to sleep it painfully shifts round on to the other, and when darkness falls it gratefully closes its eyes to the slides and scratches its itchy places. It is not learning, it is not even listening, it is merely indulging the herd instinct and a sense of cosy companionship in the dark. It is this middle section we have long desired to reach. We are paid to communicate our experience to these young minds, to lay our burden of knowledge at their feet, to pass on the torch. Till now our oratory, our sarcasm, our highly polished witticisms, and our depth of erudition have alike failed to project our personality beyond the front row. At last, however, we have found the answer.

In the January number of *Family Doctor* some exhilarating experiments are reported in which university students were given words to memorise. Without warning the light went out, the backs of their chairs fell off and the arms became electrified. In addition a revolver was fired and a sheet of iron fell to the floor. This is the technique for us. "Mark my words!," we shall roar. "You, sir, at the end of the fourteenth row, what have I just been saying?" And as we press the appropriate button the floor of his seat will give way, a bucket of water will fall on his head, and he will automatically be precipitated down the gangway to our feet. "Let this be a lesson to you, sir" we shall say sternly, as we speed him back to his place with a well-aimed revolver bullet. It beats us why we didn't think of it before.

* * *

Strange as it may seem, one often finds that even the queerest remarks of the psychiatrists have a grain of truth in them. I remember some years ago how a psychiatrist friend was trying to explain how he had got over his dislike of the phone ringing at night. He was a rather incoherent Irishman and at the end of his monologue all I could discover was that he had solved his problem by stuffing an old sock into the bell. I hadn't an old sock handy and anyhow I treated his idea with contempt. But three years later I found there was something in it. It isn't the call itself which is so disturbing. It is the sudden loud ring of the bell. Now I leave the bell switched through to the surgery at night instead of to my bedroom. I still hear the bell perfectly, waking perhaps at the second ring instead of the first. It disturbs the family no more than before, but to my mind the slightly more gradual awakening takes away the initial alarm and sense of urgency which a sudden awakening brings. Others may not be affected in the same way, but I commend my idea to fellow sufferers. Incidentally, why didn't the psychiatrist explain more fully in the first place? I suppose he wanted to make me think it out for myself. It worked in the end, but it seemed to be doing things the hard way.

* * *

One small but psychologically important job which the new College of General Practioners might tackle is the retention of the family doctor's "copyright" in his more interesting patients when the latter are written up as published cases by hospital staffs. The decline to vanishing point in acknowledgments to general practi-

University of Oxford

Prof T Pomfret Kilner has been appointed Nuffield professor of surgery in succession to the late Sir Hugh Cairns

Mr Pomfret Kilner is a graduate of Manchester and London Universities At Manchester he was Dauntesey scholar and Sidney Renshaw exhibitioner and he won medals in anatomy and physiology before graduating M B with distinction in surgery and pathology in 1912 He took the London degree in the following year After serving with the R A M C in the 1914–18 war he was appointed plastic surgeon to Queen Mary's Hospital for Face and Jaw Injuries Sidcup, in 1919, and he became F R C S in 1921 In the years following he was appointed plastic surgeon to many hospitals including St Thomas's Hospital London, Manchester Royal Infirmary and Birmingham United Hospitals and he took charge of the plastic surgery division of the Ministry of Pensions In 1935 he was a Hunterian professor of the Royal College of Surgeons He took up his present appointment as first Nuffield professor of plastic surgery at Oxford in 1944 when he became head of the new department of plastic surgery

The appointment of Dr Alice Stewart as reader in social medicine has been approved for the years 1953 to 1959

Order of St John of Jerusalem

British Association of Plastic Surgeons

At the annual meeting of this association in December the following officers were elected for 1953

President Mr J N Barron hon treasurer Mr R P Osborne, hon secretary Mr J P Reidy council Prof T P Kilner Sir Archibald McIndoe Mr Rainsford Mowlem, Mr G M FitzGibbon, Mr J S Tough Mr D N Matthews (vice president), Mr A B Wallace (editor)

Renal Association

This association is to hold a meeting at the Ciba Foundation, 41, Portland Place, London, W 1, on Jan 28, at 4 P M , when Mr A W Wilkinson will speak on Biochemical Changes after Transplantation of the Ureters, and Mr D Innes Williams on Long term Results of Transplantation of the Ureters for Ectopia Vesicæ

Patient Selection

Speaking at Cardiff on Jan 5 at the beginning of his four-day tour of Wales, Mr Iain Macleod, the Minister of Health, said that too many people were in hospital who ought not to be there and too many people were not in hospital who should be (*Times,* Jan 6) He believed this could only be put right by closer integration between the local authority and the hospital authority "I am not satisfied" he added, "that we have found the right relationship between local authorities and those rather arbitrarily appointed regional boards"

CORRIGENDA *Persistent Hiccups*—In our annotation on this subject (Dec 27, p 1262) we erroneously referred to the phrenic nerve as arising from thoracic roots This nerve originates in cervical roots

University of Sheffield—Dr T M Abbas has been appointed lecturer in obstetrics and gynæcology, and not senior lecturer as we reported last week

---

EMERGENCY BED SERVICE—In the week ended last Monday applications for general acute cases numbered 1836 The proportion admitted was 84 41%

CORRIGENDUM *Steribac*—On Dec. 13 (*Lancet* General Advertiser p 2) we printed an advertisement of Messrs Clay & Abraham's Steribac solution for the storage and sterilisation of surgical instruments and needles By an oversight we gave the price wrongly The correct price is 3s 9d for 20 oz and 12s 9d for 80 oz

10 30 A M (King's College, Strand, W C 2) Scientific pap

l-chair she described her own initial inexperience of the se, which was epidemic in Cleveland this year, what she ially learned, what plans should be made for the future, the different ways in which the disease started and its different results. She recounted her own initial symptoms e fears they aroused, her reactions to those fears, and the going to bed. When paralysis set in she believed all was ith her. She was sure she felt short of breath at times she had nightmares about artificial respirators. Her ors varied. Then, when paralysis receded her hopes rned, and although left with some disability she described t she could do, what sort of careers were still open to her, what long-term care was going to mean.

he third case was of a young working man, married, fit, had never been ill before. He described an attack of te lobar pneumonia which had brought him to hospital an emergency a few weeks previously. The results of mination and treatment were described and illustrated and parison made with the disease and its effects as between '30s and '40s of this century. The development of motherapy and the antibiotics was sketched in.

The whole afternoon went with a swing and three rs passed without notice. I talked with students erwards and it was obvious that their enthusiasm had en roused. Terminology had been simple and that re were many aspects of illness was clearly appreciated. e student said to me "I'll never forget it." Another d apologetically "I feel dedicated already." I myself s deeply impressed. Here we had young people ginning their medical career who were introduced to k people on their third day in college. They were own that illness is an intricate affair which could be oked at in many different ways. The implications of ness and the doctor-patient relationship were portrayed, and the prime importance of the basic sciences as there for all to see. The whole afternoon was refully planned and the contributions of the staff re thoughtful, clear, and sympathetic. To me it was great improvement on the traditional address with a gh-sounding title delivered by some distinguished sitor. The hoary old themes of art and science, medical manism, hippocratic tradition, changing patterns, tegration and disintegration, specialism, the *profession*, ospect and retrospect, theory and practice, which orn the columns of our journals at the opening of each ademic year, seem unsuitable and unhelpful to the new udent.

There is much more that could be said about the estern Reserve experiment. No-one there is dogmatic. taff coöperation has been remarkable, and authoririanism, that stumbling-block of the curriculum atin: "race chariot!") is laid flat. And how!

Cardiff.

JOHN D. SPILLANE.

PITUITARY EXTRACT IN OBSTETRICS

SIR,—Professor Nixon and Dr. Schild (Jan. 3) call ttention to the very real danger of giving whole posterior ituitary extract in obstetric practice. The toxic vasoressor factor, in addition to its toxic action on the oronary vessels, invokes a rise in blood-pressure which ay be unfavourable or fatal. Unfortunately the loose se of the word "pituitrin" may cause it to be given hen these vasopressor actions have serious ill-effects.

Some years ago a new house-surgeon delivered a rimigravida who had hypertension and albuminuria hich had appeared just before labour. He ordered a c.c. of pituitrin," and within a short time the patient tarted having eclamptic fits. There was no doubt that he vasopressor part of the posterior pituitary extract ad raised the patient's blood-pressure and precipitated he eclampsia.

In my hospitals we use pituitary extracts very little ecause ergometrine has such a reliable action and ecause the oxytocic effect of injectio oxytocini, *B.P.*, r 'Pitocin' is so variable. But we have had to make rrangements to prevent the pituitrin accident recurring. The hospital pharmacist no longer supplies the extract of posterior pituitary to the maternity department, but he does provide injectio oxytocini, *B.P.* ($^1/_2$–1 ml. or 5–10 units), or the similar preparation, pitocin. Furthermore, if anyone uses the term pituitary extract or pituitrin, whether he be a member of the staff or an examination candidate, I take up the word and ask him whether there is any doubt of his using the word correctly.

London, W.1.

ALISTAIR GUNN.

ORAL ANTIBIOTICS AND SPONTANEOUS HÆMORRHAGE

SIR,—Dr. Payling Wright's letter[1] prompts me to report a case of spontaneous hæmorrhage due to hypoprothrombinæmia occurring within 48 hours of the administration of aureomycin.

The patient was a primigravida at term, who developed a concealed accidental hæmorrhage with complete suppression of urine from the moment of onset. When she was first seen five hours later, the fœtus was dead; there was no urine in the bladder, and none had been voided since before the onset of the catastrophe. The blood-pressure was 160/110 mm. Hg. A lower-segment cæsarean section was performed, and a typical large retroplacental clot was discovered; there was no evidence of retroperitoneal hæmorrhage.

The anuria was treated by the method recommended by Bull et al.[2] Diuresis commenced on the sixth day. On the twelfth day the patient developed basal pneumonia, which was treated by aureomycin. By this time she was having a moderate diet by mouth, and had had 6 pints of packed red cells by three separate transfusions. Forty-eight hours later the patient developed a large spontaneous hæmorrhage into the abdominal wall, which burst the healed abdominal wound, and multiple purpuric spots over the body. The blood-prothrombin time by the Quick method was over 100 seconds. The condition was treated by injections of vitamin K continued for some days. Thereafter the patient made an uneventful recovery.

Galway, Eire.

D. T. O'DRISCOLL.

BUTAZOLIDINE AND SALT EXCRETION

SIR,—In view of the widespread use of butazolidine, a preliminary report on one aspect of its toxicity —i.e., œdema—and on the comparison of its clinical effect with that of cortisone does not appear out of place.

14 patients with rheumatoid arthritis were put on a salt-free diet, and then 7·5 g. sodium chloride per day was issued as a ration. The total daily urine was collected for a preliminary week, for one to two weeks during which the patients had 600–1200 mg. butazolidine per day, and for a subsequent week; and in 7 cases the results were compared with a period during which 75–150 mg. cortisone was administered.

In 11 of the 14 cases there was slight retention of sodium on the first two days of administration, and in the remainder there was a similar period of retention about four days after treatment was started. After this initial decrease in excretion the levels fluctuated; but in 6 cases there was a distinct increase in salt excretion directly butazolidine was discontinued, and in 5 others this peak excretion occurred on the eighth to tenth day of treatment—as not uncommonly happens during cortisone treatment. At no time during this experiment was any change in excretion of uric acid observed, although the usual increase was found when 2 of the cases were checked with administration of salicylate. The clinical response did not correlate with the excretory pattern in this group of patients. In this series of cases no gross œdema occurred; and neither in these cases nor in others where œdema developed has any albuminuria or hæmaturia been produced.

7 patients subsequently received cortisone. Of 3 who gave a poor clinical response to butazolidine 2 also

2. Bull, G. M., Joekes, A. M., Lowe, K. G. *Ibid*, 1949, ii, 229.

Orthopædic and manipulative surgery, including such things as the repair of hernias, the treatment of hæmorrhoids, and the various ways in which a gynæcologist can rescue a middle-aged woman from chronic invalidism—all these have been of incalculable benefit In much the same category are the developments in traumatic and plastic surgery which made it possible to say in 1945 that any wounded soldier reaching hospital alive had an 80% chance of survival and almost as good a chance of being capable eventually of earning his own living

On the medical side the change is not so striking, but our maintenance therapies—insulin for diabetes, liver or B_{12} for pernicious anæmia—are in a sense analogous to the surgical or prosthetic triumphs I have mentioned

In the whole application of surgery to human disease and disability there have been four great discoveries anæsthesia, aseptic technique, blood-transfusion, and antibiotic control of infection from within The art of the surgeon is to use his knowledge, his ingenuity, and his craftsman's skill to apply these discoveries to each individual problem There is infinite scope for improvement in methods of cutting and manipulating body tissues with the safety made possible by the four great discoveries, but for the most part what is needed is men to make the best use of what is available rather than to find new approaches In regard to surgery I believe that there is perhaps one important field still to be fully explored—namely, means of dealing with the complex functional conditions which cause death from shock Otherwise the whole field is one for clinical rather than fundamental research

The Gaps in the Present-day Picture

The great advances in the hundred years, then, are the virtual elimination of infectious disease and malnutrition as major causes of death, the provision of prosthetic or surgical help for bodily defects, effective surgical treatment of traumatic, mechanical, or infective emergencies, and a wide variety of symptomatic remedies, particularly means of diminishing pain Two important types of maintenance therapy to make good a gradually developing genetic weakness have been successful in diabetes and pernicious anæmia, while a third type is or may be emerging in the treatment of rheumatoid arthritis with cortisone

What are the major medical problems which have not been effectively dealt with? The first and most important is of course insanity and feeble-mindedness, probably the next *is functional disease of the nervous system*, with its manifestations in the psychoneuroses and psychosomatic disorders It would be in line with modern thought to add that crime, delinquency, and general bad manners are hardly distinguishable from the medical manifestations

We may look at the matter from two points of view (1) the major remaining causes of untimely death (i e, of persons dying under 60 years of age), and (2) the main reasons for individuals being incapable of normal economic activity

In the first group we have

(a) *Death of infants* in the first month of life from various forms of congenital malformation or disability

(b) *Death from cardiovascular inefficiency* of one sort or another, with coronary disease taking an increasingly important part

(c) *Cancer*, the incidence of which increases steadily with age but is still of great importance under 60 years

(d) *Death from violence*, especially automobile accidents

Many of these will also be responsible for a more or less prolonged period of social dependence before death ensues, especially cancer and a variety of cardiovascular conditions In civilised countries of Western European origin the major causes of disability for which there are no clearly defined preventive or curative procedures are

(1) Manifestations of *genetic anomaly*, of which p anæmia and diabetes almost certainly are example shall point out later, this group may include in part s almost every human disability

(2) *Psychogenic disorders*—i e, disease caused or p tated by emotional factors On the one hand we hav orders of behaviour and personality, on the other the so psychosomatic diseases—conditions in which by one m nism or another the emotional difficulty leads to ph lesions that may range from backache and skin comp to essential hypertension, exophthalmic goitre, and p ulcer

(3) *Allergic disturbances, representing essentially a dis* of the immunity mechanism Rheumatic fever and prob rheumatoid arthritis, nephritis, and some forms of asth may be related to bacteria as the sensitising antigen multiform assemblage of troubles—hay fever, asthma a many types of skin lesion—may be associated with n bacterial sensitisers

(4) There remain many conditions where it is impo to say that any single cause is responsible—gall stones a kidney stones, obesity, chronic bronchitis, varicose veins, a many others

In general, therefore, methods are well developed f dealing appropriately with the impact of tangi environmental agencies on the body—micro organis infection, trauma, poisonings These are things wh are easy to understand, which can be reproduced animals, and which have provoked the combination laboratory work and clinical ingenuity that has b responsible for most of our successes in medicine

Where we are at a loss is to assess and compensate f the influence of factors intrinsic to the patient Eve human being who is not one of a pair of identical tw is uniquely *different from every other* human bei Probably every single one of us has genetic charact which he would be healthier without And every doc will agree that in *one way or another* the patient's "co stitution" is concerned in his every illness Also intrin to the individual in the sense I am using the word is emotional attitude toward his environment A ma temperament is probably very largely inborn, but at a given point in his life it is what his life's experience h made of his inherited make up There is no doubt th many diseases are psychogenic in origin—i e, they wou not have occurred if the patient had not been exposed *worry, frustration, and other* non-material impacts the environment Equally we can feel certain th there are people whose inheritance is such that no co ceivable amount of frustration or fear would ind peptic ulcer or chronic colitis Finally we have recognise that death *is a* necessary end—a unive evolutionary necessity—and to die is as much part our inheritance as to cease growing at 18 or 20 T healthiest of men finds his tissues hardening and fail as he passes 70, and in one place or another the fin breakdown will come eventually The rate of sen degeneration in different tissues will vary from pers to person, presumably mainly for genetic reasons

From this point of view, once we get away from th extrinsic causes of disease and disability we face a vast more difficult problem The patient presents us with disease condition whose nature is determined (1) b certain aspects *of his genetic constitution*, (2) by h past experience, which may well include a sequence o low-grade impacts from the environment, and (3) t psychosomatic components, which in one form or anoth will always be there

In contrast to the "extrinsic" *disabilities*, these a complex and difficult to understand—they can b reproduced in animals only in rather crudely and d tantly analogous forms—and at the present time the is virtually nothing we can do to prevent their occurre There is no short cut to their understanding via th laboratory bench, they can be tackled only by the dire study of the human material *But these are the* problem

The question of representation of whole-time con- its on the staff side was also discussed at some length. s pointed out by our deputation that there was not a whole-time consultant employed by a regional hospital l on the staff side, and that therefore there had never available to the staff side of Whitley Committee B the e of anyone competent to speak for the whole-time nal board consultants.

e would like to state that we received an extremely pathetic hearing from the staff side of Whitley mittee B, and it is realised that one of the greatest ; to progress has been the predominating influence he Ministry of Health and the absence of an arbitra- agreement either within or without Whitley Council.[2]

DANGER OF PHENOL WITH PENICILLIN

SIR,—The hazard demonstrated by Dr. Aronson, Leys, and Dr. Swift (Dec. 20) can be avoided by eful supervision of all injectable solutions. It is, or ould be, normal practice for the pharmacist who epares the solution to indicate on the label the nature d concentration of any added bacteriostatic. Injections ould not be prepared by a nurse, for this and other asons. The *British Pharmacopœia* directs that solutions medicaments intended for intrathecal, intracisternal, peridural injection shall not be sterilised by heating ith a bactericide, nor issued in multi-dose containers, hich may be taken to mean any containers closed with a ncturable rubber cap. The force of the latter pro- sion is that solutions in multi-dose containers are variably required to contain bacteriostatic substances.

The golden rule for safety is that intrathecal solutions, hatever their nature, shall be drawn from sealed glass mpoules, and from no other type of container. Normally e pharmacist will prepare such solutions with rigid sepsis, transfer them to sterilised ampoules, and seal em by fusion of the glass. When stored, preferably r periods not exceeding 48 hours, they are refrigerated. mpoules, warmed to blood heat, should be scratched ith an *efficient* file or diamond point before opening, avoid contamination with glass spicules.

There is one serious objection to intrathecal injections repared directly in a rubber-capped vial of antibiotic. e have satisfied ourselves in this hospital that fine articulate matter is by no means rare in solutions so repared. Furthermore, rubber fragments may be resent, or may be introduced by the needle used for ithdrawal; they constitute a serious hazard. Ampouled olutions, examined in a powerful indirect light before eing passed for issue, have given no such trouble.

Southmead Hospital, Bristol.

PETER COOPER.

SPLENOMEGALY IN SCARLET FEVER

SIR,—Dr. O'Reilly's letter in your issue of Dec. 20 as very interesting.

A few years ago while stationed at an R.A.F. hospital saw about 80 cases of scarlet fever, all in young men ged 18–20 years. Of these, 7 were found to have alpable spleens.

In each case the spleen was firm and not tender; and it was ever enlarged beyond three finger-breadths below the left ostal margin. In most cases the enlargement was noticed on dmission to the wards and subsided slowly during the ollowing fortnight, although in 1 case the spleen was palpable s long as four weeks after the onset.

All the cases of scarlet fever were mild, and there was no ifference between the symptoms of those with palpable pleens and those without. Total and differential white lood-cell counts and Paul-Bunnell reactions were performed n all the cases of splenomegaly, and in none was there any hæmatological evidence of infectious mononucleosis.

Some 300 cases of tonsillitis and upper respiratory infections were seen during the same period. In none of these was splenomegaly recorded. Throat-swabs from all the cases of scarlet fever and a large number of the cases of tonsillitis were cultured; and almost invariably these yielded hæmolytic streptococci, which were, however, not typed. As might be expected perhaps, a rather high incidence of rheumatic fever was found on this station, which was a recruit centre; but no obvious correlation was found between this and the incidence of splenomegaly.

In general practice I have since seen two or three children with tonsillitis who have had palpable spleens.

Wolverhampton.

D. P. FITZGERALD.

HEPATITIS

SIR,—Your encouragement of clinical and epidemiological observations of hepatitis [1] prompts me to comment on the American studies [2 3] to which you referred in the light of work done in England.[4]

The American observations of anicteric cases in young children and of symptomless infections revealed by liver-function tests are an extension of Pollock's [5] demonstration of a positive Hunter's test for bilirubin in the urine of apparently healthy young children during an outbreak in a residential nursery.

The lack of effect of isolation of "suspected children" on the spread of infection in the American epidemic may have been due to the occurrence of infectivity during the early part of the incubation period (25–35 days [4 6]). Infectivity at this time was thought to account for an explosive outbreak in some wards of an institution for mental defectives.[4] Infectivity is usually greatest shortly before and after symptoms appear, as is shown by the few cases where transmission by a short and single exposure has allowed the identification of the time at which a case was infectious, and by the general experience that successive cases in close contacts in the family [7] or in Army units [8] commonly occur at intervals of approximately one month.

The disease in young children is rarely as severe as in the cases reported by Wylie and Edmunds.[9] In England in several outbreaks in day and residential nurseries there were no severe cases, and in epidemics in villages deaths from acute yellow atrophy were very few and occurred in children of school age and in adults. In families where a case occurred, young children were usually not ill at all, though parents and grandparents quite frequently became jaundiced.

The suggestion [3] that infective hepatitis virus may be a cause of "infantile diarrhœa" is not in agreement with my experience in England, where (1) in a hospital with hepatitis endemic in nurses there was no undue incidence of diarrhœa in infants in maternity and children's wards, and (2) in several outbreaks of "infantile diarrhœa" there were no cases of hepatitis in nurses in the hospital at the relevant time. From the data available, it is more likely that the diarrhœa in the American children was due to some other virus and a precursor of the hepatitis cases in the same way that epidemics of typhoid,[10] intestinal infections,[11] and upper respiratory infections,[12] have preceded some epidemics of poliomyelitis.

At the medical level most bacteriology today is almost confined to the great commercial drug houses, which alone have the resources to undertake the systematic and effective study of the thousands of possible compounds that might be used therapeutically Microbiology is a flourishing science in the universities and research institutes, but except to a limited extent it has almost wholly deserted the medical field The most flourishing aspect of bacteriology is what is called microbial genetics, and though this is throwing much light on the basic processes of life its bearing on the treatment and prevention of disease is almost nil Those of us in the virus field have rather more responsibility from two points of view First viruses are rather liable to flare up into sudden unexpected epidemics large or small Our Australian encephalitis epidemic in early 1951 was an example on a small scale, and the 1918-19 pandemic of influenza on a world-wide one The second justification is that a study of the interaction of virus and cell may throw light on the cancer process Cancer is certainly not a virus disease in any reasonable sense, but there *are* virus like agents associated with some types of cancer I have often said that a virus is the most subtle probe we have with which to explore the interior of the cell When we know a lot more about the interior of the cell we may find an effective clue to the processes which turn a normal into a cancerous cell—or we may not

That leads me to cancer research On the one hand we have every variety of study into cell processes of a wide range of organisms—any one of them *may* add a contribution of value to cancer work, but 99% or more will certainly not do so On another angle we see the attempt to find agents which will selectively damage or kill cancer cells but leave normal cells unaffected Radiations (X ray, radium, and artificial radioactive isotopes), a variety of poisons like nitrogen-mustard gas and chemically distorted nutrients, and viruses "trained" to attack cancer cells only—these are the three main lines of research today I am not in very close touch with cancer work, but I am much impressed by the difficulty of the problem and I feel rather pessimistic about the prospects of gaining any significant influence over the mortality of cancer for many years to come I might guess that the most useful way to diminish cancer incidence would be to close the cigarette factories

There is not likely to be any great change from the present rule that the best hope in cancer is early diagnosis and appropriate treatment by surgery and/or radiation therapy

In the field of what we may call metabolic diseases—i e, such maladies as diabetes, pernicious anæmia, and rheumatoid arthritis—there is great activity in the application of known methods to the clinical problems that arise But there is little likelihood of major changes of approach, and even smaller likelihood that there are other major diseases in which hormonal deficiencies of this general type are concerned Though we deal, or attempt to deal, with these diseases on physiological and biochemical principles their origin is almost certainly genetic Future developments in their understanding, though not necessarily in their control, will come when the genetic approach is properly exploited

I wish that I could say something hopeful about research into disease of the nervous system, whether its manifestations are physical or mental With some minor reservations the position today is much the same as it was in my student days when every patient with a physical disorder of the nervous system was given antisyphilitic treatment The basis was simply that if the disorder was due to syphilis it might be cured, if not, it was certainly incurable There is admittedly much being done at an empirical level in treating mental disease by the very crude procedures of leucotomy or the electrical or toxic shock treatment Both procedures have their uses but they are obviously onl transitional approaches to problems of almost insup- difficulty

In the laboratories there is great activity in the of the nervous system, and most physiologists now are electrophysiologists The immense comm development of electronic equipment in recent years provided gadgets of infinite adaptability for the m ment of electrical changes in nervous tissues ingenious experimenter can find an infinity of prob to study He can also take pride in the way his is joining hands with that of the makers of "elect brains," and introducing "cybernetics" to the phi sophers It is magnificent, but it has no bearing what on the pressing problems of insanity, behaviour d orders, and feeblemindedness Probably every sci has felt at times that most other scientists are guil the sin of infinite and futile elaboration I am al feel that way about electrophysiology, but I must admit that from the president of the Royal Soc downwards electrophysiologists have the highest sta today in the scientific world

I am not competent to discuss psychological psychiatric research Like most scientists outside th special field, I find it impossible to digest what of th psychological literature there is time to read As biologist I fancy that the effective generalisations th are needed may eventually be found more readily fr the study of animal behaviour than from too undu an attention on the

We can be sure tha persists, resear on all these aspects of medicine, from infectious dis to psychiatry, will go on They will change their chara mainly in response to the discovery and utilisation of t techniques

But all the work that I have discussed is from a point of view at a superficial level It has been concer only with the body and mind as we find them It is the essence of all the problems that body and mi have arisen by a process of evolution In the broad sense genetics can be defined as the science concer with the transfer of pattern from one generation another, pattern of bodily structure, pattern of behavi and in humans and domesticated animals pattern disease I turn therefore to what I feel will be th important topic of medical research for the futu human genetics

The Central Place of Genetics in Modern Biolog

There has been a general attitude of defeatism in regard to medical genetics Every doctor will ad that inheritance plays a part in every illness, but there is nothing that can be done to alter it he usually feel that there is no sense in attempting to st the genetic aspects of the illness more closely This i perfectly justifiable attitude to the clinical problems today—but not, I think, a correct one

Let us begin by considering the main types of gene study now going on

We all know that the inheritance of all human char teristics is determined by the sorting out of chromosom that takes place when germ cells mature and then fu in the process of fertilisation There is great activit in the study of problems of this sort in plants a animals For historical and accidental reasons a lar amount of the theoretical research has been done on tw organisms—one a little fruit fly, drosophila, the other a important food plant, maize Most of the agricultural important plants and animals have been and are be studied genetically with both theoretical and practi aspects in mind The most important commerc application has been the development of hybrid corn the United States In most types of stockbreedi theoretical genetics has been helpful in rational

I was quite a little girl"; and she described a typical of acute otitis media. On that side the radiogram ed the cells with patterns similar to the other—but again dentical, because all the cells were smaller, with thicker between them.

each practising otologist finds one such case in the se of his career we may, in a century or so. have a ectable body of evidence in favour of this hypothesis.

ngfield, Surrey. T. B. LAYTON.

BOVINE TUBERCULOSIS AND HUMAN TUBERCULOSIS

IR,—Mr. Pitcher's thesis (Dec. 6) is, to a first approximation, perfectly logical. The argument runs thus:

1) Pulmonary tuberculosis is due almost exclusively to ction by the human type of tubercle bacillus.

2) There is a high degree of cross-immunity between man and bovine tuberculosis. Therefore, a diminution in ections due to the bovine tubercle bacillus will increase number of people susceptible to both types, and, other ngs being equal, will lead to an increased incidence of lmonary tuberculosis. Mr. Pitcher's figures purport to show at this theoretical possibility has been realised in Scotland.

Before considering Mr. Pitcher's data, let us remember at bovine tuberculosis is not to be regarded merely as beneficent immuniser against infection by the human acillus: bovine tuberculosis was estimated to have used some 2600 deaths in 1931.

Mr. Pitcher's tables compare notifications for 11 ounties in two quinquennia. In his first table the second uinquennium is virtually the same for all counties, but r the first quinquennium he chooses five different eriods. I do not wish to suggest that Mr. Pitcher has isled us by *choosing the periods to support the thesis.* o doubt his choice was governed by availability of data, ut he should certainly try to show that his results have ot been sophisticated thereby.

It seems to me that at least the first table contains rrors of simple arithmetic. The last column, "increase r decrease," seems to have been calculated as a simple ifference, and this would be legitimate if, as is probable, he populations of the counties did not alter greatly etween the two quinquennia. If my assumption be orrect, then the last column figures for West Lothian nd Dumbarton should read +119 and +12 respectively. t may be that Mr. Pitcher has made his calculation by ome other method, in which case the figure which he ives for Dumbarton may be correct, but that for West othian is certainly wrong on any basis of computation.

Finding the rates for Glasgow incredible, I have taken he liberty (which I hope Dr. Laidlaw will forgive) of xtracting the real figures from the annual reports of the lasgow medical officer of health. They are as follows:

Year	*Population*	*New registrations of pulmonary tuberculosis*
1930	1,088,810	1687
1931	1,088,461	1702
1932	1,095,263	1722
1933	1,103,357	1616
1934	1,115,590	1523
1946	1,075,000	2809
1947	1,100,000	2765
1948	1,110,000	2775
1949	1,110,000	2829
1950	1,100,000	2446

It follows from these figures that the notifications per 100,000 population were 152 and 247 respectively, and not 2 and 3 as Mr. Pitcher states. It is possible that the terms "new registrations of pulmonary tuberculosis" and "notifications" are not quite synonymous; for example, the first term might include "transfers in," but this could not account for the gross discrepancy.

Apart from the unreliability of the data there is a fundamental defect in the logic of Mr. Pitcher's argument. The immunological consideration which underlies his argument is whether or not *living* tubercle bacilli are ingested. The extent to which a milk-supply is pasteurised or sterilised is, therefore, of the first importance. It means very little to say that 50% of the milk consumed by a community is from non-attested herds if in fact the bulk of this 50% is adequately heat-treated before consumption; unless of course, Mr. Pitcher intends to argue that the ingestion of killed tubercle bacilli can produce immunity. For this there is, so far as I know, not a scrap of evidence.

D. B. BRADSHAW
Leeds. Deputy Medical Officer of Health.

Obituary

THOMAS DRUMMOND SHIELS

Kt., M.C., M.B., Edin.

Sir Drummond Shiels, who died in London on Jan. 1, had made a career for himself in politics as well as medicine: and he had used his experience in each calling to enrich his work for the other.

He was born in Edinburgh in 1881 and when he left school began work as a photographer. During the 1914–18 war, while in command of a trench-mortar battery, he was mentioned in despatches and was awarded the M.C. and the Belgian croix-de-guerre. After the war he returned to Edinburgh and began to study medicine, taking his M.B. in 1924. Meanwhile he had been elected to the Edinburgh town council, and in the year he graduated he also became a Labour member of Parliament for East Edinburgh.

[Walter Stoneman

His political advancement was rapid. In 1927 he was appointed a member of the Royal Commission on constitutional reform in Ceylon. Two years later he became Parliamentary under-secretary for India, and later to the Colonial Office. After he lost his seat in Parliament in the 1931 election he became secretary to the British Social Hygiene Council, a post for which his judgment and turn for lucid exposition well fitted him. But the decision not to seek re-election to Parliament had been a hard one, and he eagerly seized the opportunity, when it arose, to join the staff of the Empire Parliamentary Association. As deputy secretary of that body he was brought back to the atmosphere of Westminster in which he thrived, and which gave scope for his genial personality. In 1946 he was appointed public relations officer to the Post Office, and in the same year he also became a member of the Colonial Economic and Development Council. He was vice-president of the Royal Empire Society, on whose council he had served for many years, he was also a member of the governing body of the British Postgraduate Medical Federation. He was knighted in 1939.

R. F. writes: "The Clydesiders considered Drummond Shiels's views to be pale pink, but they never questioned the honesty and sincerity of purpose of their Edinburgh colleague. The inevitable ins-and-outs of the politician's life meant for him hardship and financial stringency, but he never complained, and he always showed those qualities of toleration, loyalty, and humour for which he was held in general esteem. In speech he was slow, deliberate, and almost ponderous, but he never took himself too seriously. If his demeanour was grave, his smile at once removed all trace of the funereal. His manner was tactful and persuasive, but that jowl of his denoted dour persistence: his humour was pawky rather than sly, for there was nothing but good nature behind it. At home in any company, he never forgot that he was a Scot: and when he presided over his fellow-exiles at the dinner of the London Burns Club in 1951, we little guessed that his life of public service and private kindliness was so near its end."

Sir Drummond Shiels's first wife died in 1948. In 1950 he married Miss Gladys Buhler, M.B.E., who survives him with the daughter of his first marriage.

become recognisable There are two important practical implications here The first is that by early recognition of such premonitory signs we may be able to institute a régime that will delay the full or fatal expression of the disease, the second is that it may allow a more accurate prognosis of the life expectation of individuals for any sort of actuarial purpose

4 It would provide a magnificent and varied clinical training for a succession of young doctors passing through the unit giving an approach to patients as full human beings that tends to be lost when men are trained in clinical research too closely at the physiological level

5 With the extension of such work over the whole medical world there would slowly develop a consciousness of the importance of inheritance, an accurate knowledge of the mode of inheritance of the common as well as the rare and striking human genetic anomalies, and an understanding of what can and cannot be accomplished by conceivable forms of control of human reproduction

6 As in every type of effective research, there would arise new ideas and approaches which until the work is done are quite literally unthinkable It is even possible that ways of preventing genetic deterioration may be found that could be tolerated by a free human community

This brings me to my final point—that sooner or later ways *must* be found to reverse that process of genetic deterioration of our species that is demonstrably in process at the moment

As a biologist I regard it as certain that man has evolved by the same process as other living organisms, as a doctor and for my present purpose I am concerned only with the health of the body The evolution of tradition and civilisation is outside our province and uniquely human The evolution of the body and of the defects of the body falls within the realm of genetics Mendel's laws hold for man, there are biochemical mutants in man as well as in the moulds and bacteria that the microbial geneticist studies Equally we can be certain that the line of mammalian evolution that led up to man was directed by the same process of gene mutation, recombination of gene patterns, and natural selection that can be seen at work in organisms susceptible to direct genetic investigation Mutation by its very nature must normally be harmful—the mutation or combination of mutations leading to improvement of the type must inevitably be rare Progressive evolution, in Fisher's words, is a miracle wrought by selective survival in the teeth of a storm of deleterious mutations

If man is outside the workings of Nature, if his continuing progress toward his own bodily and spiritual ideal is predestined and determined by supernatural means, then what I am saying is meaningless and unnecessary But if we accept the working hypothesis of scientific medicine that man is wholly a part of Nature and that his diseases can only be understood and remedied in the light of comparative biology, then I think we have got to face the situation realistically

It has been estimated that the harmful mutation to hæmophilia occurs once in 50,000 births Most hæmophiliacs have little chance of passing on the altered gene, and the symptomless female carriers would gradually diminish in number unless fresh mutations occurred But as Muller has pointed out, if a maintenance therapy like insulin for diabetes was discovered which allowed hæmophiliacs to lead a normal reproductive life, nothing but deliberate human action could prevent a slow but inexorable increase in the proportion of hæmophiliacs until they became a majority of the human species Every deleterious mutation which in one way or another does not prevent or diminish the fertility of those carrying it must eventually spread through the race like a slow-moving infectious disease Somehow some means must be found to counteract the present trend by which the unhealthiest elements in the population of Western countries reproduce more rapidly than the healthy I have already mentioned the evidence that in England the one measurable aspect of human value—intelligence—is falling at the rate of 1 6 points per generation. democratic welfare State may have its virtues transitional compromise, but unless it finds an to the problem of genetic deterioration it will be doo In my gloomier moments I feel that a case might be for the thesis that it will be the descendants of the race to receive the blessings of civilisation who eventually rule the world In the old days of birth-rate and very high infant mortality many hea babies died, but almost certainly more of the genet unsound than the sound and thus there was some au matic control of quality Today the combination of two child family and preventive medicine has prod a situation highly desirable on the short term view b on the long-term biological view leading straight catastrophe

There is no *politically possible* way of remedy this at present, but at the back of everything I h been saying is my conviction that here is *the* great t of future medical research—to plan the ways by w the bodily health and intelligence of human b may last from generation to generation It is a t for centuries rather than decades but the sooner it started the better I hold no brief whatever for a present interference with the traditional but sp taneously changing pattern of human mating a reproduction We know far too little, and wh knowledge there is is far too little known to peo generally The task of the next hundred or even fi *hundred years is to gain the knowledge and* educa the people till effective action at length becom possible.

THE LATE RESULTS OF REPAIR OF LARG HERNIAS WITH TANTALUM MESH

D M Douglas
M B E, Ch.M St And, F R C S F R C S E
PROFESSOR OF SURGERY IN THE UNIVERSITY OF ST ANDRE

An experimental study of the reaction of living tis to tantalum mesh, together with a preliminary repo *on its clinical use, was published in this journal four yea ago (Douglas 1948)* The late results of the repair of *cases of large or recurrent hernias are now presented*

DETAILS OF OPERATIONS

The details of the operations for incisional an umbilical hernias are seen in figs 1 and 2, which are s explanatory It is most important to achieve a go overlap of fascia over the implanted mesh In the cas of inguinal hernias in males the testis was transpo through the conjoined tendon in the manner of Schnede (1934) to avoid pressure of the edge of the mesh on th spermatic cord

MATERIAL

13 inguinal, 8 para umbilical, and 15 incisional hernias have been operated on (see table) Most were larg hernias considered by colleagues unsuitable for repa by other methods The remainder were recurrent hernias, no primary small hernias were treated wit tantalum mesh

CASES OF HERNIA REPAIRED WITH TANTALUM GAUZE

—	Type of hernia			Total
	Inguinal	Para umbilical	Incisional	
No of cases	13	8	15	36
Postoperative deaths	0	0	1	1
Death from other diseases since operation	2	0	2	4
Untraced	2	0	0	2
Recurrence	1	0	0	

Notes and News

THE WORK OF THE N.A.P.T.

HE better success we are having at present in preserving uberculous from early death must not blind us to the fact for every one who dies of the disease in any year. 5 or 10 ll. The National Association for the Prevention of Tuber- sis is thus in no danger of losing its occupation for some to come. The annual report [1] for 1951–52 notes how much k the voluntary tuberculosis care committees still do for ients—even though the tuberculous now have a legal right such things as extra milk, new bedding, or (if need be) a poration house and a sheltered job. Yet "one's legal nts in this world are seldom quite sufficient," and, as the A.P.T. points out, the voluntary committees can help ients in ways which are not legally open to local health horities—by subsidising them financially, for instance, or in a case quoted in the report) by providing for the training an unsuspected talent. The N.A.P.T. acts as a consultant ntre for these voluntary bodies, giving them advice about y, administration and procedure. A piece of social research anced by the association is being carried out in Scotland Mrs. J. F. Wilson. She will assess the social effects which diagnosis of tuberculosis and the subsequent treatment has the patient, his family, and his relations with the com- unity; and it is hoped that the study will give information out the use made of the health services, the gaps in it, the gree of disruption of family life produced by the disease nd the social handicap it imposes. The N.A.P.T. is also oviding bursaries of £100 yearly for men and women who tend, or propose to attend, the university, and whose reer has been interrupted by tuberculosis; the first award as made this year. Other scholarships have been awarded nurses, to enable them to visit Denmark, Norway, and weden to study tuberculosis control there.

A semi-documentary film *Personal Episode* has been made or showing to the general public, with the intention of putting ne subject of tuberculosis in a sympathetic light, and emoving some of the apprehension felt about sanatorium ursing. The setting is Scottish, and the story is of a girl tudying to be a teacher, at Edinburgh University, who reaks down with tuberculosis, goes to a sanatorium, recovers, nd decides to become a nurse. The N.A.P.T. has renewed n arrangement, in action before the war, by which district nurses and Queen's nurses from rural areas are able to take a course of 4–8 weeks in postgraduate training at one of the arger tuberculosis hospitals, and has also arranged for ectures to medical audiences: last year, for instance, lectures were given in Inverness and Lewis by Dr. Marc Daniels (on treptomycin and B.C.G.), and in Lewis by Mr. F. J. Sambrook Gowar (on lung resection for pulmonary tuberculosis).

The membership of the N.A.P.T. is divided into sections, which are more or less autonomous, some active groups being he medicolegal section, the sanatorium matrons' section, and he nurse teachers' section. These arrange their own meetings and lectures for themselves. Art therapy continues to be very popular, and art competitions are held four times a year. There are some 500 entries on each occasion and it takes the selection committee a week to judge the entries and dictate their criticisms. Besides being good for the patients, this should in time contribute to a revival of painting in England as stirring as the revival of music achieved by the B.B.C.

Besides these and many similar undertakings fostered by the association, a great annual stream of books, pamphlets, leaflets, and journals proceeds from the N.A.P.T., nourishing the growth of sound ideas about tuberculosis, and fertilising the minds of doctors as well as of laymen.

HELPING THE LONG-STAY PATIENT

THE preparatory training department of the British Council for Rehabilitation helps long-stay patients in hospital and long-term convalescents in their own homes to prepare themselves to earn their living when they are once more fit. The department arranges for them correspondence courses, supplemented so far as possible by supervisory visits, and where possible tuition by a visiting instructor. Every course is arranged subject to the approval of the patient's doctor. The department works in coöperation with local education authorities who refund tuition fees and help in other ways. Patients are also encouraged to contribute to the cost as their means permit. Courses in 250 subjects, ranging from secretarial work to radio engineering, and from commercial art to criminal psychology, have been provided by the department or through one of the local affiliated committees which are being formed throughout the country.

Further particulars may be had from the registrar, Preparatory Training Bureau, British Council for Rehabilitation, Tavistock House South, Tavistock Square, London, W.C.1.

PROPOSED AMENDMENT TO ABORTION LAW

ON Feb. 27 Mr. Joseph Reeves's Abortion Bill is due for second reading in the House of Commons. But, as it is preceded by two other Bills, it is doubtful whether it will be reached.

The Bill adds the following proviso to section 58 of the Offences against the Person Act 1861, which makes it a felony to administer drugs or use instruments to procure abortion:

> Provided that—(*a*) no person shall be found guilty of an offence under this section unless it is proved that the act charged was not done in good faith for the purpose of preserving the life of the mother; (*b*) no registered medical practitioner who acts with the concurring opinion of a second registered medical practitioner shall be found guilty of an offence under this section unless it is proved that the act charged was not done in good faith for the purpose of preventing injury to the mother in body or health.

HOSPITAL STATISTICS

THREE weeks ago, in a critical review [1] of *Statistics of the Hospital and Specialist Services for England and Wales* for 1950, a correspondent mentioned that the next volume in the series was to appear very shortly. It has now been published,[2] and the Ministry of Health hopes in future to present the *Statistics* "by the middle of the year following the one to which they relate."

The 1951 volume gives figures for over 3000 hospitals and clinics which are either part of the N.H.S. or linked with it under contractual arrangements. It is possible, for example, to find out how many staff in any of over 40 categories—from consultants to laundry staff—were employed in any particular hospital at the end of 1951. Other information given in respect of every hospital is: bed complement; number of beds available; average daily bed occupation; total of inpatients who died or were discharged during 1951; total of new outpatients; and total attendance of outpatients and at casualty departments.

PRODUCTION OF A.C.T.H.

MANUFACTURE of A.C.T.H. in Britain has been started by Crookes Laboratories Ltd. Supplies of this substance, which is being made from the pituitary of home-reared oxen, are expected to satisfy home demand; and it is also to be exported.

POISONS LIST AND RULES

REVISED versions of the Poisons List and the Poisons Rules came into force on Jan. 1. The changes in the list are set out in schedules to the Poisons List Order, 1952,[3] which also includes the current list in full. The Poisons Rules, 1952,[4] consolidate with amendments the rules issued in 1949, 1950, and 1951.

University of London

The following have been successful in examinations for the degree of M.S. (branch 1, surgery):

Claude Brun, W. D. Corfield, D. H. Jenkins, P. F. Philip, M. C. T. Reilly, H. H. Renyard, J. J. Shipman, K. W. Wilkinson.

University of Manchester

Dr. T. R. Malloy has been appointed lecturer in child psychiatry.

National Association for Mental Health

At a meeting of this society to be held at the Royal College of Nursing, Cavendish Square, London, W.1, on Friday, Jan. 16, at 2.30 P.M., Mr. Claud Mullins, the former Metropolitan court magistrate will speak on Crime and Mental Health.

Recurrence 1—A man, aged 56, had a large right scrotal hernia with a widely dilated deep inguinal ring The Schmieden manœuvre was used, *the testis and cord being transposed* through the conjoined tendon Within eleven months of this operation *a small bulge appeared at this site, and this has* become a little larger over the last four years The patient does not wear a truss

Recurrence 2—A woman, aged 35, had a recurrent right inguinal hernia It was difficult at operation to *find in the* region of the inguinal ligament sufficient tissue under which to countersink the *mesh The recurrence is in the form of* a diffuse bulge over the operation site and causes some discomfort

In the remaining 27 cases there has been no recurrence, and it is of particular interest that in none of the incisional or para-umbilical hernias has a recurrence been noted. There have been no discharging wound sinuses after the use of this technique, though in a series of cases which we are now studying in which nylon mesh was used there have been 2 cases of discharging sinuses

DISCUSSION

Inguinal Hernia

The method is clearly *not good for inguinal hernia,* the reason, I think, being that it is difficult in recurrent cases to find enough tissue inferiorly to anchor the mesh securely. Further, in males there does not appear to be any satisfactory method of fitting the gauze snugly round the issuing spermatic cord The Schmieden manœuvre obviously carries its own special risk of recurrence through the new deep inguinal ring

Incisional and Para umbilical Hernia

In view of the size of the hernias dealt with and the absence of recurrence in this group the method is clearly of value In the past I have found it difficult to close any defect in the abdominal wall greater than 7 cm in diameter by any technique If the edges are pulled together with silk, fascia, or nylon, the sutures simply cut through the living tissue as they would through cheese With mesh there is no such problem Flaps are turned in from the edges of the defect, allowing the first layer to be closed easily without tension, the resulting defect is next filled with tantalum mesh

Fracture of Mesh

As the result of repeated bending the mesh ultimately fractures This does not seem to influence the result of *the repair, probably* because the strong fibrous tissue layer has grown through the framework of the mesh *But the ends of the wire gave rise* to an uncomfortable pricking sensation in the woman in whom a recurrence was noted She was very thin, and perhaps there was insufficient subcutaneous tissue to cover the fractured edge of the mesh *She was the only* patient who complained of this sensation I had thought that the late results of these herniotomies would be less satisfactory than the immediate results, but this follow up study has shown this to be untrue Both recurrences were seen within a year of operation

SUMMARY

36 large or recurrent hernias have been repaired with tantalum mesh, the shortest period since operation being 4 years, the average 5 years

There have been two recurrences, both in inguinal hernias

There have been no recurrences in para-umbilical or incisional hernias

No wound sinuses have developed

The method is of little value in inguinal hernia but may be used with confidence in large incisional and para umbilical hernias

CLINICAL ASPECTS OF THE TOXICIT POLYMYXINS A, B, AND E

P N SWIFT
M R C P
PHYSICIAN TO CHILDREN'S DEPARTMENT, FARNBOROUGH HOSPITAL, KENT

S R M BUSH
M Sc Brist, PhD Lo
PHARMACOLOGIST, WEL RESEARCH LABORAT BECKENHAM, KE

THE polymyxins are polypeptide antibiotics d from different strains of *Bacillus polymyxa* Five h been described and are designated by the alphab suffixes A to E They are *bactericidal and at le* hundred times more active against most gram neg *bacilli than against the gram-positive organisms* (Br lee et al 1952) Although there were early repor their clinical use (Swift 1948, Schoenbach et al 19 polymyxins A and D have not become popular, ow probably to the introduction of antibiotics with w antibacterial spectra and to the attention focused on t proteinuria associated with the parenteral injectio polymyxins A and D, but recent reports (Yow 19 Jawetz 1952, Swift and Bushby 1951, Jackson et a 1951, Tomlin 1951, Kagan *et al* 1951) on the effic of the polymyxins in certain types of meningitis, uri *infections, and burns, especially when the infect* organism is *Pseudomonas pyocyanea,* have reawak interest in these antibiotics

As a class, polypeptide antibiotics have undesir side-effects which often render them unsuitable f parenteral use, and our early experiences with p myxins A and B suggested that they were not exceptio Proteinuria, ranging from a trace to 0 2 g per lit developed in 26 of 27 children given polymyxin A *doses of 4000 to 10,000 units per kg of body* wei four-hourly for five days Relatively impure polymyx B* in similar doses given to 24 children, and in doses 250,000 units given to 8 adults caused no proteinur but caused severe reactions at the sites *of injecti* pyrexia up to 102°F, malaise, and in 3 *of the* adu paræsthesia In contrast, our more recent experienc with polymyxin E and with purer preparations polymyxin B have shown that these polymyxins a suitable and safe for parenteral use, and, since there now little doubt that the polymyxins are potent chem therapeutic drugs, we are prompted to record observations on the side effects produced in 61 pati treated with these two polymyxins

RESULTS

Polymyxin E—Forty-seven patients, including adults, were given intramuscular polymyxin E four hour for five days Seven of these had longer courses of fou teen days or more for *Hæmophilus influenzæ* meningi along with intrathecal injections of doses ranging fr 25,000 to 100,000 units once or twice daily for from fi to fifteen days For children individual doses were bas on the scale of 10,000 to 12,500 units per kg of bod weight The dosage for adults was 250,000 units exce in 2, when it was increased to 500,000 and 1,000,0 units (see below)

In contrast to our earlier experiences with polymyxin and polymyxin B the toxic effects from polymyxin were few and trivial and caused little discomfort to t patient Protein, red cells, and casts appeared in t urine of 1 child only This child, under treatment f *H influenzæ* meningitis, died from an intercurre infection, and the case has been described elsewh (Swift and Bushby 1951) *Microscopy of the kidne* revealed that the secretory epithelium of the kidne

THE FUTURE OF MEDICAL RESEARCH*

Sir MACFARLANE BURNET
D. Melb., Sc.D. Camb., Ph.D. Lond., F.R.A.C.P., F.R.S.
ECTOR OF THE WALTER AND ELIZA HALL INSTITUTE OF MEDICAL RESEARCH, MELBOURNE

MEDICAL research is a very human activity carried out men of diverse types who have entered and stayed the field for a variety of reasons. It has a history and continually changing approach to its material. Like e broader field of scientific research of which it is a rt, it has developed its own sense of values and a nviction of its own intrinsic importance. These do t always coincide with the ideas of the community nerally. It has grown out of human need, but its ajor contributions to human welfare have mostly come by-products of its own intrinsic activity—an intrinsic tivity which nowadays has almost lost contact with cial need.

My object here is to consider in what directions edical research must develop if it is to be of maximal se to the community—having due regard to the fact at there is a well-defined cultural pattern of research hich like any other established pattern of tradition and ctivity cannot be changed suddenly without dire onsequences.

This puts the problem neatly into two halves. What oes the community need from medical research ? And ow can the present pattern of research activity be more ffectively directed toward those socially valuable ends ?

The Aims of Medical Science

The aim of medicine in the broadest sense is *to provide or every human being, from conception to death, the greatest ullness of health and length of life* that is allowed by his enetic constitution and by the accidents of life.

We are all aware of the importance of preventive as ell as curative medicine, and we are equally aware of ow indefinite is the boundary between social amelioration and preventive medicine. A rising standard of iving, and the spread of "upper class" demands for omfort and of "upper class" habits of cleanliness hrough the community, have been the most important actors in the vast increase in health and length of life hat has taken place since the middle of last century. lorence Nightingale is perhaps the key figure of that hange. Aristocratic, religious, neurotic, and with a errifying capacity for work, she realised that the physical omforts of food, space, cleanliness, and good manners hat were available to her own class were the important hings lacking in the handling of the sick and wounded oldier or the sick pauper. Since then public health has lways included an interest in housing and working onditions and all that complex of social philanthropy nd regulation which in our day has flowered into the "Welfare State."

Medical research in any ordinary sense has had little r nothing to do with this social revolution, which, I hould guess, has been responsible for at least half the mprovement in the expectation of life that has taken lace in the last hundred years. Florence Nightingale never believed in bacteriology, and, though in due course he bacteriologists found good reasons for the benefit btained by improving drains and supplying pure water, he whole process was well under way before the scientists had any influence whatever in administrative circles.

I have perhaps unduly stressed this point because I eel that when we are considering the social aspects of medicine we have to recognise that health depends on more than a regard for the bodily well-being of the individual as such. To give a current example—if in India or China the rapid application of known techniques produced an immediate reduction of infantile and general mortality to a Western level, within ten years there would be an intolerable strain on the food resources of the world and famine in the countries concerned.

I suggest that we need to add an even broader concept of the rôle of medicine in the modern world. Out of the idea of public health there is growing the concept of human biology with its own central objective. Perhaps this can be stated as simply to find means *to ensure the indefinite continuance of the human species at a level of physical and mental health not inferior to that of the present.* It is perhaps characteristic of the present time that we have reduced our aspirations for the future to such a negative statement. But I think we are realising every year the complexity and the difficulty of accomplishing the task that I have stated. Its implications go into every phase of human life—politics and economics even more than medicine. But here I shall try to confine myself to aspects bearing directly on the bodily health of human beings, including mental and social factors only in so far as they affect the body.

Our modified definition of the aim of medical science, then, is to provide for all human beings the greatest possible health and length of life and to ensure that the possibility of providing those benefits shall not diminish from generation to generation.

The Changing Problems of Medicine

A hundred years ago the major causes of premature death resulted from infectious disease and malnutrition, especially in infancy and childhood. Infantile mortality in London then was near 300 per 1000 live births. Improper food and infectious disease of one sort or another were mainly responsible.

Infectious disease will always be with us, and there will always be room for further refinement in prevention and treatment; but as a major cause of death in the years of youth and maturity it is becoming relatively unimportant. Similarly the knowledge we have of the fundamentals of nutrition is such that the problems in that field are wholly educational and economic. Scurvy and rickets are virtually unknown in Australia where our only important nutritional disease, tooth decay, is due not to a food deficiency but to excess of a luxury.

Though it may seem an inappropriate remark for one whose whole professional life has been concerned with infectious disease, I believe that, provided the established mechanism of preventive medicine, medical care, and drug production continued to function, fundamental work on the nature of micro-organisms and on the diseases they produce could stop today without influencing the current process by which all the main infectious diseases except poliomyelitis are disappearing. This is of course an over-statement: as long as the human race exists there will be long-term changes and sudden new episodes of infectious disease that will need intelligent investigation and appropriate action to counter them. My point is only that it is extremely unlikely that any new principles will be needed to maintain our present very effective control of infectious disease; in that sense fundamental research is not called for by an expressed human need. I can leave you to make precisely the same sort of qualification about nutritional disease.

Apart from the disappearance of infectious disease and gross malnutrition, the main changes in the medical scene in the last hundred years have been the provision of means for minimising physical or functional defects of the body, whether congenital or acquired.

Spectacles, false teeth, and hearing-aids may be slightly comic, but they have probably done more for human happiness than any other application of medical science.

---

* From a lecture given before the Actuarial Society of Australasia at Melbourne on Sept. 11, 1952.

restricted to the tubules, and only when there is proteinuria are high concentrations of the antibiotic excreted in the urine (Brownlee et al 1952) This evidence suggests that the nephrotoxic polymyxins A, C, and D pass through the normal glomerulus and damage the tubule during resorption Polymyxins B and E, on the other hand, do not usually cause renal damage and are present in the urine in low concentrations It is therefore a reasonable conclusion that it is the molecular configuration which permits or prevents passage through the normal glomerulus

Some of the subjective side effects of the polymyxins may be due to histamine, for the intradermal injection of polymyxin in man produces a typical histamine triple response, and Kagan et al (1951) found that the subjective side-effects of the polymyxins were relieved by anti-histamine drugs Experimentally, however, no significant quantity of free histamine can be detected in polymyxin Nevertheless polymyxin may cause the release of endogenous histamine, since the intravenous injection of 20,000 units per kg of body-weight into dogs often produces a pronounced and sustained fall of blood-pressure closely resembling that produced by the powerful histamine-release drugs—e g , 48-80 (Paton 1951)—and an increase of histamine can be demonstrated in the blood (Bushby and Green 1953)

All these side-effects have been reported before, but their frequency has varied according to different reports Kagan et al (1951) comment especially on the variability in the reports of the toxic reactions of polymyxin B Referring to the pyrexial reactions they draw attention to the fact that of five separate workers only one noted pyrexial reactions and these in 62 of 66 patients Most reports, however, agree that the polymyxins B and E seldom damage the kidneys

It is unfortunate that the first polymyxins in man should have been the polymyxins A and D, which attracted publicity by their effect on the kidneys The use of the group name, polymyxin, has also led to confusion, thus Hayes and Yow (1950), who successfully used polymyxin B in the treatment of infection with *Ps pyocyanea*, state that Schoenbach et al (1949) noted the commonest complication of polymyxin therapy to be renal damage, whereas the workers cited were referring only to polymyxin D

After oral administration all the polymyxins are poorly absorbed (Brownlee et al 1952), and in 12 children with gastro-enteritis treated by us with polymyxin A 40,000 units per kg of body-weight four-hourly for 5-8 days no toxic side effects were observed Although polymyxin is effective in the local treatment of infected burns, absorption from such surfaces is poor, for no polymyxin is detectable in the blood, and no toxic symptoms are produced, when 1% polymyxin E ointment is used (Jackson et al 1951) The side effects observed by us after intramuscular administration occur only when the antibiotics are given by this route Our experience shows that although polymyxin B and E cause some side-effects, these are not serious, causing at the most only temporary discomfort to the patient The most troublesome of these subjective effects is the pain that persists for some hours at the injection site, this is less with polymyxin E than with polymyxin B, but is so mild that the use of these antibiotics can be confidently recommended

SUMMARY

Polymyxin E given parenterally to 53 patients, and polymyxin B given parenterally to 32 patients, caused no proteinuria, this contrasts strongly with the high incidence of proteinuria produced by polymyxins A and D

Early experiences with polymyxin B showed that it caused troublesome reactions, especially pain at the injection sites, and in some patients pyrexia, malaise, and mild paræsthesia The incidence of pyrex malaise seems to be smaller with purer material

Polymyxin E caused less pain at the injectio than did polymyxin B, but the incidence of paræs was about the same

It is suggested that the different side effects o polymyxins are due to differences in molecular stru and that some of the subjective effects are due to release of endogenous histamine

Although the side-effects from parenteral polymyx and polymyxin E may be annoying to some pat they are not, especially with polymyxin E, sufficie contra-indicate their use

ANALYSIS OF THE NORMAL ELECTRO-ENCEPHALOGRAM

N W Ellis

A M I E E , A M Brit I R E

RESEARCH WORKER IN ELECTRO ENCEPHALOGRAPH, RUNWELL HOSPITAL, ESSEX

S L Last

M D Berlin L R C P E , D P M

PHYSICIAN-SUPERINTENDENT, ST JOHN'S HOSPITAL, STO BUCKS

For some years electro-encephalographers have bee occupied with the problem of differentiating quantit tively between normal and abnormal electro encephal grams (E E G) Because of the complexity of the materi the characteristics of the E E G have mostly been asses by direct inspection of the primary trace and measur ment of trace height wherever a single frequen appeared in the record, description of the component par being based largely on qualitative assessment Metho have been evolved to quantify the material (Davis a Davis 1936, Hoagland et al 1937, Golla et al 1943, Lo et al 1944), but none of these has been widely adopte Several methods of wave form analysis have be developed for this application (Grass and Gibbs 193 Knott and Gibbs 1939, Gibbs 1940, 1942, Barbour 194 Hoefer et al 1949, Prast 1951, Krakau 1951).

Here we report on the results obtained in a norm population with the automatic wave analyser devis by Grey Walter (Walter 1943a and b, Baldock a Walter 1946) Our material consisted of fifty men ag 20-58 and fifty women aged 17-61, who were eith members or relations of the staff of the hospital

METHOD

Electrodes were so placed that on either side o similar areas were bridged , of these the fronto occip frontal, occipital, and precentral transverse posit have been used for this study Bipolar recordings ma medical research must face in the future—and we have to make a considerable reorientation of our of medical research to do so.

The Pattern of Medical Research Today

would hold that science springs from the same root raftsmanship and art, and I should define science simply as the systematisation of methods for the t effective satisfaction of human desires. But with development of research and scholarship as a profes al occupation, science has become a pattern of llectual techniques and judgments of values, with a archy of prestige and a subtly graded system of ards. In many ways the modern community of ntists has as definite a social structure as the medical fession or the Protestant clergy. It is a structure that well adapted to the functioning of those who compose I doubt if there is any other human activity in which wards are so closely related to the value of the work ne, or in which the typical and most sought after ward is the opportunity to do more and better work.

All scientific activity springs from the drive to satisfy uman needs and desires, but in finding the most effective eans of doing so scientists have become on the whole ore interested in the means than in the end. To do a ing properly demands an understanding and control many relevant factors, each of which in turn depends others. Any experimental scientist of imagination nd intelligence can start with any problem whatsoever, nd by following where it leads spend a lifetime in eritorious scientific work. There is a tradition well unded in experience that important advance in practical s well as in theoretical science comes not from the direct ttempt to cater for some practical need but by working t the advancing edge of knowledge. Very often nowa ays the procedure is to apply to the advancing edge of ne field, ideas or techniques that have been developed a different field.

Being an academically minded scientist myself, I know hat the typical research man is happiest when he has all he materials for his experiments or observations immedi tely under control. It is much more gratifying to study pidemics in mice, where everything from the strain f virus to the diet of the mice is known, than to try to nake sense of a human epidemic, where all the factors re intrinsically complex and are made worse by health lepartments taking all sorts of action to stop it.

There are of course many people engaged in applied esearch in industry, agriculture, medicine, and sociology; ut it is inescapable that in the cultural pattern of cientific activity this ranks lower than "pure" science. am making no personal value-judgment here: I am nerely reporting the fact that in scientific circles generally t is the development of ideas and generalisations on a asis of sound experimental work that gives status, not he production of life-saving drugs or money-spinning nventions. Take the recent presidents of the Royal ociety—Rutherford, Bragg, Robinson, Sherrington, Dale, Adrian, a wonderful sequence of names—men who ave influenced enormously the development of know edge and in many indirect ways the practical life of the ommunity. But none of them have produced by their wn work discoveries or techniques that were immediately aluable to industry or medicine.

The academic point of view might be expressed in its xtreme form by saying that scientific research is an ctivity of value for its own sake, and that, provided the project is attacked by the accepted methods of experimentation and logic, the actual material investigated is quite unimportant—so long as it is of such a nature as to uncover ideas and generalisations applicable to more than the situation actually studied. A good example is Sonneborn's studies of the genetics of the protozoon paramoecium. Paramoecium has no conceivable "useful" interest to human beings. It has a faint resemblance to some pathogenic forms, but that is all. Nevertheless we academic biologists all agree that this work of Sonneborn's is of first-rate theoretical importance. This is the type of value-judgment that runs through scientific work today, and which has become an integral part of the pattern of science.

In practice most fields of scientific study are chosen with some regard to the possible human implications of the work. For fundamental studies of how viruses multiply in cells I feel happier in using the virus of human influenza than I would in using a virus acting on some common bacterium. But the general approach to the problems, and the satisfaction of discovery when it came, would be precisely similar in the two cases.

What I want to stress is that one cannot present a scientist or group of scientists with an important human problem—let us say the cause of breast cancer—and expect a straightforward advance to an acceptable answer. What is allowable is to ask that an investigation be undertaken in some field which in the light of current knowledge seems relevant to the human problem. There is, for instance, much current interest in Bittner's ideas about a virus-like agent being responsible for breast cancer in mice. It would be reasonable to apply the mouse techniques to a series of cases of human cancer, or to study the interaction in mice of the "virus" factor with such things as age of infection or influence of hormones. For progress to occur we are almost compelled to have a number of individuals or groups working on the problem in different parts of the world and cross-stimulating one another with their different approaches.

Even a very young scientist knows nowadays that the chances of his discovering something equivalent to penicillin, nuclear fission, or the cause of cancer are vanishingly small; but he also knows that if his intelligence, curiosity, pertinacity, and imagination are up to the necessary standard there is a well-defined path by which he can make a continuing series of contributions to knowledge and in the process gain prestige and reasonable economic security. He will be disinclined at any stage to step off that moving staircase and adopt an attitude to science out of line with the current tradition.

I am not saying that this is a good thing: I think in fact that in many ways it draws some of our best brains away from the fields where they could make their best contribution to human welfare. There must be many first-rate academic scientists who if their interests lay that way could make a far more effective contribution in industry or practical medicine. But it does represent the pattern of today's high-grade scientific activity. And it must be remembered in any attempt to mould research activity toward what the community or any influential section of it feels is needed. Every major applied research organisation finds that if it is to keep its best men these must have opportunity for the fundamental work that brings them satisfaction and prestige of the sort they cherish. Experience suggests that a first-rate man is more useful if he is contented, even if he is in fact not primarily interested in the job that he is paid for.

All that this adds up to is that it would be quite foolish to lay down even the most enlightened programme for medical (or any other type of scientific) research and expect it to be carried out in that form. Sometimes under stress of urgent need a man will find the drive to go straight ahead for a definite and limited objective, but that is by no means the usual approach.

Current Activity in Medical Research

Once medical research was almost synonymous in the lay mind with bacteriology; and certainly it is in the field of infectious disease that laboratory research has had its main practical triumphs.

women shows an almost symmetrical distribution about the peak frequency of 10 cycles per sec

Side —The curves for the right and left occipital areas are shown in fig 3 Side differences have been described (Brazier and Finesinger 1944, Cornil and Gastaut 1947), but, because of differences of technique, comparison with our results is not profitable In our findings it is noteworthy that the differences between the right and left sides are similar to those existing between men and women This side/sex correspondence has been found in other fields (Holt 1949)

Areas —The considerable difference between areas is illustrated in fig 4 The dominance of the alpha activity occipitally is in accordance with generally accepted findings The activity in the precentral area is maximal in the higher frequency range with a peak at 20 cycles per sec, the secondary peak at 9 cycles per sec is evidence that, even this far forward, the alpha rhythm is not inconsiderable Theta activity reaches its maximum in the frontal lobes, though the fast group of frequencies is still the dominant component, as in the precentral area

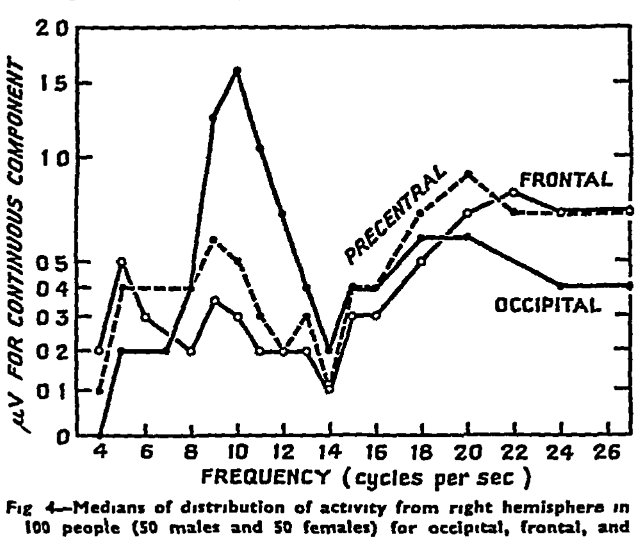

Fig 4—Medians of distribution of activity from right hemisphere in 100 people (50 males and 50 females) for occipital, frontal, and precentral transverse derivations

Frequency Intercorrelations

The method of treatment of the material so far presented has masked completely individual patterns and effects An attempt was therefore made in this study to assess the relationships between frequencies and groups of frequencies within individuals to see whether specific patterns or associations emerged Calculations were made to obtain correlation and intercorrelation products between amplitudes at all frequencies measured The accompanying table, which shows the combined results for both hemispheres of our 100 cases, illustrat[illegible] the value of this sort of study The following are th[illegible] main features of this mixed grouping •

(1) The correlations within the band of theta frequenc[illegible] (4–7 cycles per sec) are high and positive, showing that it [illegible] usual for these components to rise and fall together

(2) There is a positive correlation between the band [illegible] theta frequencies and 14 cycles per sec and, to a lesser degre[illegible] 15 cycles per sec This association, if unexpected, is [illegible] particular interest

(3) The individual frequencies in the alpha range [illegible] remarkably independent of other influences and show li[illegible] correlation with anything except their immediate neighbour[illegible] Activity at 8–10 cycles per sec is, in fact, marked by a hi[illegible] proportion of negative values

(4) Frequencies of 16 or more cycles per sec show a w[illegible] and progressively increasing spread of association with [illegible] frequency

These findings will want further analysis with separa[illegible] tion of areas, sides, and sexes, but they show how [illegible] normal pattern of correlation can be established

SUMMARY

The electro encephalogram of 100 normal adul[illegible] divided equally for sex have been investigated with [illegible] automatic low-frequency wave analyser

The several techniques used for treating the result[illegible] are described

Distribution diagrams and curves of activity in th[illegible] range of frequencies from 4 to 27 cycles per sec are show[illegible]

Comparisons and intercorrelations between sex[illegible] cortical areas, and hemispheres are illustrated

The value of a study of relationships betwe[illegible] frequencies and groups of frequencies is suggested

This work was made possible by a grant from the Medic[illegible] Research Council *We have much pleasure in thanking* Dr [illegible] Strom Olsen for his encouragement, and Prof L S Penr[illegible] for the advice and the considerable amount of help he and [illegible] colleagues have given us

rical procedures, but in general has not greatly ified breeding techniques.

recent years, however, genetics has become coned with wider fields than those of normal inheritance nimals and plants. There are three new subsciences opulation genetics, biochemical genetics, and micro- genetics—all likely to have very great influence *on* future as well as in the future. Population genetics oncerned essentially with the mechanism of evolution ow selective survival acts on populations of known etic structure to produce the sort of changes seen in olutionary series. When we discuss such matters as the intelligence quotient of children is negatively related with the number of other children in the nily and why as a result the average intelligence otient in the British Isles is probably falling by 1·6 ints per generation we are dealing with a problem in pulation genetics. When we go to the mental hospitals d find a group of congenital aments who are such nply because of the genetic absence of an enzyme henylpyruvic oxidase) in their cells we are in the realm biochemical genetics. This may well emerge as the aster biological science of the future. In the last nalysis all the changes produced by genes are expressed rough a series of chemical reactions, and there is a rowing belief that in some way each gene controls no ore and no less than a single type of enzymic action. f the generalisation " one gene—one enzyme " is finally stablished, it will represent one of those great simplifying oncepts like the idea of evolution by natural selection r the quantum theory. How far it will have practical earing on medical or social aspects of human life may be roblematical, but it will I think bear importantly on the rowing industrial fields of microbiological chemistry. ost of the activity in the third offshoot from classical enetics—microbial genetics—is at a biochemical level. he microbe is the most versatile of synthetic chemists nd by genetic study we can often learn much about the teps by which a given synthesis is made. Few people re aware that the commercial production of penicillin nly became really practicable when the microbial eneticists sorted out a high-producing variant of the ould. There are infinite practical possibilities for the rganic chemist in this field of study. Microbial genetics s not all chemical. At the present time there is a group f workers in my laboratory who have shown that nfluenza viruses can be in a sense hybridised—a henomenon which is going to throw much light on how he virus multiplies in the cell it infects.

Human Genetics

However my real concern is with human genetics. here is already one branch of medicine that is paying remendous attention to genetics in its bearing on what ven the laity knows as " Rh babies." The inheritance nd significance of the blood-groups is a fascinating ubject that interests the anthropologist, the surgeon, and he obstetrician almost equally. The understanding and ontrol of hæmolytic anæmia of the newborn is the most mportant practical application of human genetics today.

There are, however, very much more important otential applications of the genetic approach to human edicine. Perhaps the best way to introduce these otentialities is to say something about inheritance in elation to tuberculosis. For at least two hundred years octors and laymen knew that there was an inheritable redisposition to tuberculosis, but the belief was only onverted into a firm quantitatively based statement of act in 1946.

Kallmann and Reisner went through the records of New York State tuberculosis organisation to find all persons reported as tuberculous who had a twin. These reported ndividuals were the " index twins." Their " co-twins " were sought out and along with other members of their families were studied in regard to tuberculosis. The results give a very *interesting indication of the relative importance* of inheritance and environment, of nature and nurture.

No-one will get tuberculosis unless he is infected with the tubercle bacillus, but if, as in New York State, a 90% level of infection is reached by the time of early adult life, other factors are obviously of great importance. If they were environmental (nutrition, housing, parental care, for example) they should be similar within each family. We should therefore expect siblings, whether they were twins or not, to show approximately similar incidence of tuberculosis. On the other hand, if inheritance is of high importance, we should expect a correspondingly high proportion of identical co-twins of people with known tuberculosis also to have the disease while non-identical co-twins and non-twin siblings should have a much lower incidence.

Now Kallmann *and* Reisner *obtained the following figures* for relations of the index twins with tuberculosis:

Identical co-twins	87 %
Non-identical co-twins	25·6 %
Other siblings	25·5 %
Marriage partners	7·1 %

In addition it was found that identical twins very frequently showed marked resemblances in the type and intensity of the disease.

This work leaves us in no doubt as to the importance of genetic factors in tuberculosis. It is so important, in fact, that we could say that in a modern civilised environment it is possible to eliminate tuberculosis in two ways. We may (and I think we shall) get rid of the tubercle bacillus, or we could eliminate genes for susceptibility to tuberculosis by selective breeding.

In tuberculosis we have three alternatives for control —prevention by public-health measures, cure of established disease, and genetic elimination of susceptibles. We are all rightly convinced that the first of these is the most important; but, if neither the first nor the second was possible, should we be justified in neglecting the genetic approach? The question takes on very much the same form when we think of the great variety of human disease and disability not due to microbes, poisons, or trauma, and susceptible only to symptomatic treatment. To what extent are these conditions genetic in origin, and should we begin to think about their control by genetic means?

The twin-study method is capable of supplying the answer to the first of these questions in regard to any reasonably common condition. I have often suggested that this particular method of clinical research could readily be developed in any major teaching hospital. The requirements are (1) a mechanism for finding whether each patient entering the hospital had a twin, (2) funds and facilities for finding each co-twin and persuading him or her to submit to medical study on those aspects relevant to the condition for which the index twins had sought treatment. About 1 in every 80 births is a twin birth, and, allowing for the higher mortality among twins, about 1 patient in 50 coming to hospital will have a living twin. Of these about 30% will be identical twins, 70% non-identical. At the Royal Melbourne Hospital there are about 65,000 patients per annum. This means that 4 or 5 index twins are admitted each day and that about 300 pairs of identical twins would potentially be available for study in the year. Assuming that half the available material *could be investigated* the task would be about appropriate to keep a small full-time unit fully occupied.

Let me try to make clear what such a type of investigation could accomplish:

1. It would gradually build up knowledge about the relative importance of environment and inheritance in regard *to an increasing number of clinical conditions.*
2. With that background, the possibility of preventive action (i.e., modification of the environment) could be properly assessed even in conditions where the influence of inheritance is very strong.
3. The premonitory signs of inherited disease that precede its full expression should in many instances

only other keto-acid detected by paper chromatography in the blood samples from these patients was aceto-acetic acid, however, owing tò the partial decarboxylation which the hydrazone of this acid undergoes during the extraction and chromatographic procedures, we cannot yet estimate it quantitatively

Chromatographic separation therefore confirms our findings with the Friedemann and Haugen technique of raised blood-pyruvate levels in these three cases of subacute combined degeneration Our observation that treatment, limited to the parenteral administration of vitamin B_{12}, led to a rapid return to normal of these levels is in agreement with the earlier finding of normal pyruvate levels in six treated cases of this condition (Joiner et al 1950) We have found normal blood-pyruvate levels in one untreated case of pernicious anæmia with no neurological signs or symptoms

These findings clearly need confirmation, but our tentative conclusion that in subacute combined degeneration of the cord there is a defect of pyruvate metabolism which can be rectified by treatment with vitamin B_{12} is to some extent supported by the demonstration by Scheinberg (1951) of a diminution in the oxygen consumption of the brain in pernicious anæmia and subacute combined degeneration, the degree of which appeared to be related to the severity of the neurological involvement

SUMMARY

Raised blood-pyruvate levels were found in three untreated cases of subacute combined degeneration of the cord

Treatment with crystalline vitamin B_{12} led to a rapid return to normal of these levels

We wish to thank Dr J W Aldren Turner, Dr A C Hampson and Dr M J McArdle for permission to study and report on their cases Dr R L Waterfield for hæmatological reports, Mr D H Burchett for technical assistance, and the Medical Research Council for a grant to one of us (G R W)

CONGENITAL ADRENOCORTICAL HYPERPLASIA

A METABOLIC STUDY

A Stuart Mason
M D Camb, M R C P

C J O R Morris
Ph D, F R I C

From the Medical and Endocrine Units, London Hospital

The syndrome of bilateral adrenocortical hyperplasia, associated with pseudohermaphroditism in the female infant and with sexual precocity in the male, has been well recognised for many years It is now accepted that the sexual abnormalities of these patients are due to excessive secretion of androgen by the hyperplastic adrenal glands No metabolic disturbances were recorded in these patients until Wilkins et al (1940) reported a case of sexual precocity in a young boy who had an electrolyte disturbance similar to that of Addison's disease He died with the symptoms and signs of an addisonian crisis At necropsy both adrenal cortices were found to be hyperplastic Wilkins et al concluded that in this case the adrenals had secreted excessive androgenic hormones but insufficient salt retaining hormone

There are now several records of similar cases, both in boys and in female pseudohermaphrodites, where death from adrenal insufficiency has taken place despite gross hypertrophy of the adrenal cortices We describe here a patient with female pseudohermaphroditism, char terised by excessive adrenal production of androgen, w died in addisonian crisis Studies with adrenocortic tropic hormone (A C T H) and cortisone were carried in an attempt to elucidate the underlying physiolog disturbance in such cases

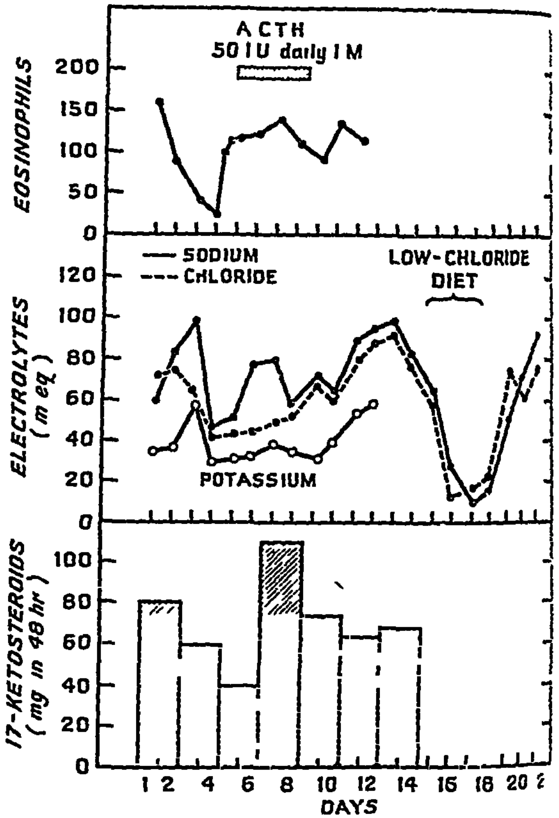

Fig 1—Response to A C T H and to restriction of dietary chlor

CASE RECORD

A girl, aged 6 years 9 months, was admitted to the Lond Hospital in September, 1950 The third of five children in normal family, she was born at full term, by normal labo and weighing 7 lb Her clitoris was noticed at birth to b larger than normal and had since slowly increased As a baby she was breast-fed and healthy, and did not vom At the age of 18 months she had a mild attack of whoop cough without any undue constitutional upset At the age of 2 years she started to have attacks of frontal headache wi nausea and vomiting, lasting two or three days and occurr every two or three months Pubic hair began to grow at th age of 3 years, and at the same age she had chickenpox an measles without complications The attacks of vomitin became more frequent and caused some prostration, b ceased altogether soon after her fourth birthday From th time she remained very well and seemed to be stronger an slightly taller than most girls of her age At the age of 5 years her 17 ketosteroid excretion was 11 mg in twenty fo hours

On examination she was 47½ in tall and weighed 60 l She was a feminine looking little girl of normal body p portions and considerable muscular strength Her skin wa normal, and she had no acne Her scalp hair was norm and she had no excess hair on limbs or face There was slight growth of axillary hair and a moderate growth of pu hair No breast tissue was palpable Her clitoris was 1 i long, her labia majora were hypertrophied, and her ureth orifice was separate from her vagina Otherwise n abnormality was found

Investigations —Radiography show a normal skull and s turcica and bones of wrist, elbow, shoulders, and kn resembling those of a girl aged about 12 years An intrave pyelogram was normal The excretion of 17 ketosteroids wa 30 mg in twenty four hours (average of four estimations by th polarographic method of Barnett et al 1946) The B fract was 4 5% (average of four estimations) rical procedures, but in general has not greatly ified breeding techniques.

recent years, however, genetics has become con- ed with wider fields than those of normal inheritance nimals and plants. There are three new subsciences opulation genetics, biochemical genetics, and micro- genetics—all likely to have very great influence *on* future as well as in the future. Population genetics oncerned essentially with the mechanism of evolution ow selective survival acts on populations of known etic structure to produce the sort of changes seen in olutionary series. When we discuss such matters as y the intelligence quotient of children is negatively related with the number of other children in the nily and why as a result the average intelligence otient in the British Isles is probably falling by 1·6 ints per generation we are dealing with a problem in pulation genetics. When we go to the mental hospitals d find a group of congenital aments who are such nply because of the genetic absence of an enzyme henylpyruvic oxidase) in their cells we are in the realm biochemical genetics. This may well emerge as the aster biological science of the future. In the last nalysis all the changes produced by genes are expressed rough a series of chemical reactions, and there is a rowing belief that in some way each gene controls no ore and no less than a single type of enzymic action. f the generalisation " one gene—one enzyme " is finally stablished, it will represent one of those great simplifying oncepts like the idea of evolution by natural selection r the quantum theory. How far it will have practical earing on medical or social aspects of human life may be roblematical, but it will I think bear importantly on the rowing industrial fields of microbiological chemistry. Most of the activity in the third offshoot from classical genetics—microbial genetics—is at a biochemical level. The microbe is the most versatile of synthetic chemists and by genetic study we can often learn much about the steps by which a given synthesis is made. Few people are aware that the commercial production of penicillin only became really practicable when the microbial geneticists sorted out a high-producing variant of the mould. There are infinite practical possibilities for the organic chemist in this field of study. Microbial genetics is not all chemical. At the present time there is a group of workers in my laboratory who have shown that influenza viruses can be in a sense hybridised—a phenomenon which is going to throw much light on how the virus multiplies in the cell it infects.

Human Genetics

However my real concern is with human genetics. There is already one branch of medicine that is paying tremendous attention to genetics in its bearing on what even the laity knows as " Rh babies." The inheritance and significance of the blood-groups is a fascinating subject that interests the anthropologist, the surgeon, and the obstetrician almost equally. The understanding and control of hæmolytic anæmia of the newborn is the most important practical application of human genetics today.

There are, however, very much more important potential applications of the genetic approach to human medicine. Perhaps the best way to introduce these potentialities is to say something about inheritance in relation to tuberculosis. For at least two hundred years doctors and laymen knew that there was an inheritable predisposition to tuberculosis, but the belief was only converted into a firm quantitatively based statement of fact in 1946.

Kallmann and Reisner went through the records of New York State tuberculosis organisation to find all persons reported as tuberculous who had a twin. These reported individuals were the " index twins." Their " co-twins " were sought out and along with other members of their families were studied in regard to tuberculosis. The results give a very interesting indication of the relative importance of inheritance and environment, of nature and nurture.

No-one will get tuberculosis unless he is infected with the tubercle bacillus, but if, as in New York State, a 90% level of infection is reached by the time of early adult life, other factors are obviously of great importance. If they were environmental (nutrition, housing, parental care, for example) they should be similar within each family. We should therefore expect siblings, whether they were twins or not, to show approximately similar incidence of tuberculosis. On the other hand, if inheritance is of high importance, we should expect a correspondingly high proportion of identical co-twins of people with known tuberculosis also to have the disease while non-identical co-twins and non-twin siblings should have a much lower incidence.

Now Kallmann and Reisner obtained the following figures for relations of the index twins with tuberculosis:

Identical co-twins	87%
Non-identical co-twins	25·6%
Other siblings	25·5%
Marriage partners	7·1%

In addition it was found that identical twins very frequently showed marked resemblances in the type and intensity of the disease.

This work leaves us in no doubt as to the importance of genetic factors in tuberculosis. It is so important, in fact, that we could say that in a modern civilised environment it is possible to eliminate tuberculosis in two ways. We may (and I think we shall) get rid of the tubercle bacillus, or we could eliminate genes for susceptibility to tuberculosis by selective breeding.

In tuberculosis we have three alternatives for control —prevention by public-health measures, cure of established disease, and genetic elimination of susceptibles. We are all rightly convinced that the first of these is the most important; but, if neither the first nor the second was possible, should we be justified in neglecting the genetic approach? The question takes on very much the same form when we think of the great variety of human disease and disability not due to microbes, poisons, or trauma, and susceptible only to symptomatic treatment. To what extent are these conditions genetic in origin, and should we begin to think about their control by genetic means?

The twin-study method is capable of supplying the answer to the first of these questions in regard to any reasonably common condition. I have often suggested that this particular method of clinical research could readily be developed in any major teaching hospital. The requirements are (1) a mechanism for finding whether each patient entering the hospital had a twin, (2) funds and facilities for finding each co-twin and persuading him or her to submit to medical study on those aspects relevant to the condition for which the index twins had sought treatment. About 1 in every 80 births is a twin birth, and, allowing for the higher mortality among twins, about 1 patient in 50 coming to hospital will have a living twin. Of these about 30% will be identical twins, 70% non-identical. At the Royal Melbourne Hospital there are about 65,000 patients per annum. This means that 4 or 5 index twins are admitted each day and that about 300 pairs of identical twins would potentially be available for study in the year. Assuming that half the available material could be investigated the task would be about appropriate to keep a small full-time unit fully occupied.

Let me try to make clear what such a type of investigation could accomplish:

1. It would gradually build up knowledge about the relative importance of environment and inheritance in regard to an increasing number of clinical conditions.
2. With that background, the possibility of preventive action (i.e., modification of the environment) could be properly assessed even in conditions where the influence of inheritance is very strong.
3. The premonitory signs of inherited disease that precede its full expression should in many instances

without any disturbance of electrolyte balance Nevertheless injection of A C T H in a dose known to cause electrolyte and eosinophil changes in a normal adult did not produce either retention of salt or loss of potassium and did not lower the eosinophil count By contrast the already excessive output of 17-ketosteroids was significantly increased These results confirm the findings of Bartter et al (1951) in 3 similar cases, and show that the physiological abnormality of the syndrome lies in the adrenal, which responds to A C T H by an increased production of androgens without significant increase in the secretion of the other adrenocortical hormones

The administration of cortisone to the patient was followed by slight retention of salt and a considerable decrease in the number of circulating eosinophils The most striking effect was the depression of the output of 17-ketosteroids to normal levels Further treatment led to a continued diminution of the output of 17-ketosteroids, and virilisation did not appear to progress The growth of axillary hair noted before cortisone was given had disappeared at death In other reported cases more intensive and prolonged cortisone therapy has led to a definite regression of virilisation and emergence of feminine characteristics (Wilkins et al 1951) If cortisone suppresses adrenal function by inhibiting secretion of A C T H rather than by direct action on the adrenal, the excessive androgen production in these cases is brought about by A C T H The presence of bilateral adrenocortical hyperplasia favours the concept of increased secretion of A C T H In an attempt to obtain direct evidence of this the urine of our patient was tested for A C T H -like activity Considerable quantities of some substance which caused severe depletion of adrenal ascorbic acid in hypophysectomised rats were found This substance was not present in the urine of normal adults

The failure of increased production of A C T H to elicit a comparable increase in adrenal secretion of metabolically active hormones must be due to some abnormality in the synthesis of hormones within the adrenal The probable nature of this abnormality is revealed by studies of the synthesis of hormones in perfused adrenals (Hechter et al 1951) The action of A C T H seems to be limited to the initial stage in which cholesterol is converted to C_{19} and C_{21} compounds The subsequent conversion of these compounds, as yet unidentified, into adrenocortical hormones is under the control of various enzyme systems of the adrenal gland These subsequent enzymic reactions are not controlled by A C T H The C_{19} precursors formed under the influence of A C T H are finally metabolised to 17-ketosteroids, and their biological activity is androgenic The C_{21} precursors are converted into glucocorticoids and possibly mineralocorticoids by the action of adrenal enzymes Therefore a deficiency of one or more of these enzymes would lead to deficient production of corticosteroids despite an adequate stimulation of the adrenal by A C T H Sayers (1950) has shown that the amount of A C T H secreted by the pituitary is regulated by the level of circulating adrenal corticosteroids on the basis of a feed-back mechanism A deficient production of these steroids will therefore lead to increased secretion of A C T H Adrenal androgens, on the other hand, do not have a significant effect in controlling the output of A C T H

The facts outlined above can explain the adrenal abnormality seen in the female pseudohermaphrodite and the male infant with sexual precocity associated with adrenal hyperplasia We suggest that the primary defect in these cases is an absence of one of the enzyme systems essential to the normal production of metabolically active adrenocortical hormones The familial incidence of the condition, its occurrence in both sexes and its onset in fœtal life make it probable that the enzyme deficiency has a genetic origin The low level of circulating corticosteroids leads to an excessive secretion of A C T H The adrenal responds to th cellular hyperplasia and the excessive product androgens Directly after birth either the baby dies f failure to elaborate corticosteroids or the secret A C T H is so great that enough vital hormone i formed through some type of synthesis to enable the to live Gross virilisation of the female and sexual prec in the male are inevitable side-effects of the att to produce sufficient corticosteroids to maintain l

Thus the condition is not considered as a prim disorder of sex hormones but as an inborn error metabolism, in which the pituitary-adrenal mechan is over-stimulated to compensate for adrenal insuffic

SUMMARY

A case of adrenal pseudohermaphrodism is report

The patient's response to A C T H was abnormal

Cortisone diminished the excessive output of 17 k steroids

Death was due to adrenal insufficiency

It is suggested that the essential lesion in these ca is the absence of an adrenal enzyme system leading t defective production of corticosterones

ADDENDUM

Since this paper was submitted Kelley et al hav reported a metabolic study of female pseudohermap rodites, and their conclusions are very similar to o (*J clin Endocrinol* 1952, 12, 1140)

PARONYCHIA

T G LOWDEN

B M Oxfd, F R C S

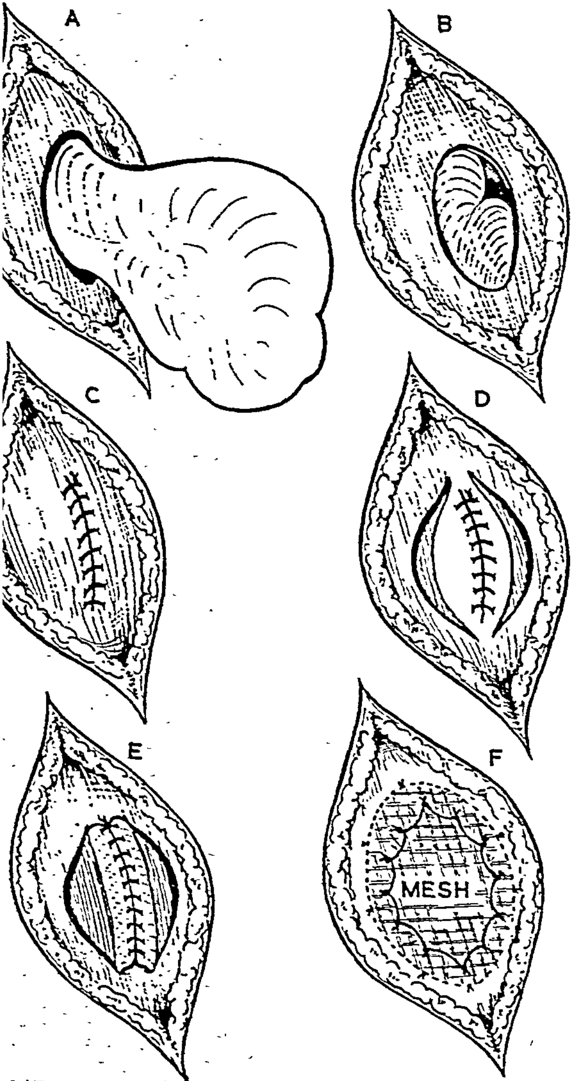
SURGEON, SUNDERLAND ROYAL INFIRMARY

IN subcutaneous infections, including those of the digital pulp space, it may be assumed that in most cases (1) the infection is due to a staphylococcus, associated occasionally with a streptococcus, (2) the longer th infection has been established, the more likely it is to have destroyed tissue with or without the development of fibro fatty slough and (3) the longer the infection has been established, the more extensive is the anatomical involvement, the larger the abscess if there is one, th more likely it is to cause skin necrosis or ulceration (Ellis 1952), and the more likely it is to produce complica tions involving bone, joint, or tendon sheath Allowance, however, must be made for the natural resistance of th patient, the virulence of the invading organism, and other variable factors—e g, the horniness of the hand, and how much it has been kept at rest The principl of treatment are based on these assumptions and sup ported by the results Penicillin reduces the length of incapacity (Pilcher et al 1948, and many others), early treatment with penicillin allows a high percentage of cases to resolve without operation, and cases coming up late for treatment show a higher incidence of bone and amples of the types of hernia dealt with are seen . 3. The average interval from operation to follow-up 5·05 years, the shortest 4, and the longest 5 years onths.

RESULTS

ere was one postoperative death in the series. A an of 50 had a very large recurrent incisional hernia e right hypochondrium. So great was the amount owel in the exteriorised sac that it was difficult to space in the abdominal cavity for it. Perhaps for reason the patient vomited a large amount of gastric ents while recovering from the anæsthetic and inhaled od deal of the material. She was bronchoscoped in an hour of the mishap, but there was gross soiling he distal bronchi. She died from bronchopneumonia the third postoperative day. This is a real hazard he repair of very large hernias. A Ryle's tube should assed before operation and aspiration of the stomach e frequently during and after operation until the ent is fully conscious.

n the remaining 35 cases there have been four late ths from intercurrent disease: one from carcinoma of rectum, two from coronary occlusion, and one from a brovascular accident. We were unable to trace 2 he patients: a vagrant of 58 who had an inguinal nia, and a woman of 53 with an incisional hernia who changed her address and left no trace. The total e-rate was therefore 34 out of 36 cases (94%).



1—Technique of repair of incisional hernia with tantalum mesh.

Among the 29 patients alive at the time of follow-up there have been two recurrences—both in inguinal hernias.

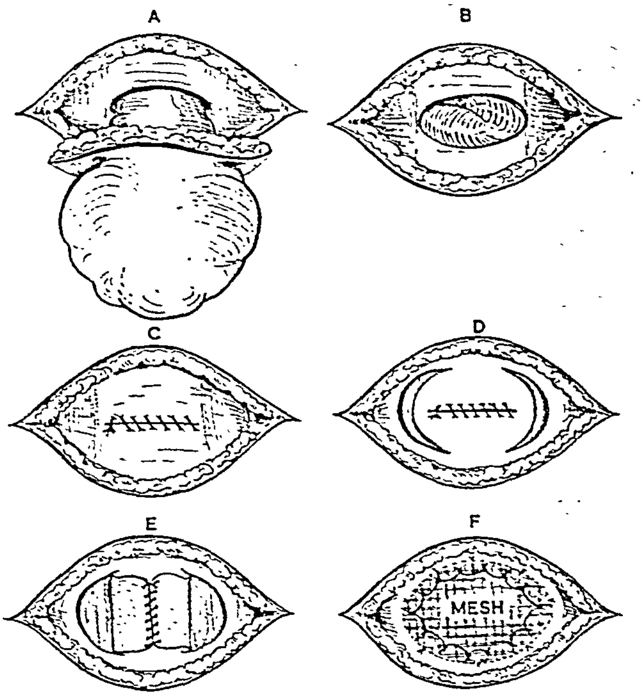


Fig. 2—Technique of repair of para-umbilical hernia with tantalum mesh.

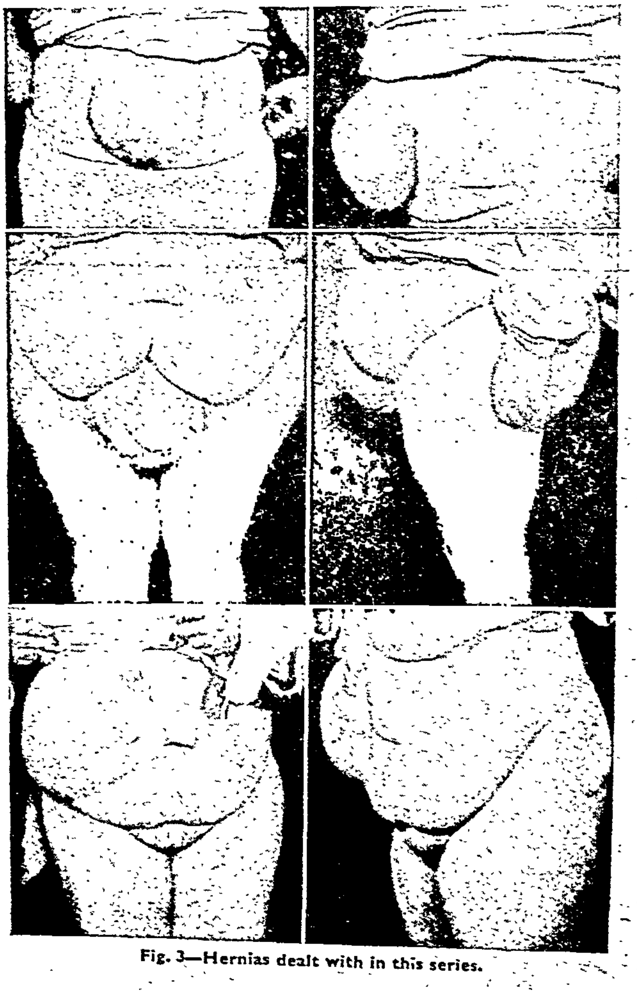

Fig. 3—Hernias dealt with in this series.

FURTHER DEFINITIONS

Certain other cases should be carefully distinguished from paronychia The *terminal pulp-space infection with distal subonychial localisation is probably a clinical entity (Bailey 1952)* It is usually included in analyses of pulp-space infections and seldom spreads as far as the nail fold or sulcus

It is sometimes a little difficult to decide whether foreign bodies under the nail should be included, because they often suppurate, and sometimes a typical paronychial infection is said to have begun when a sliver of wood was run under the nail and removed at home On the other hand, practically every case of foreign body under the nail that is seen and treated promptly heals without any spreading sepsis—even those with pus round the foreign body—and these cases present none of the problems referred to above I have therefore omitted them

COMPLICATIONS

Circulatory inadequacy is not a complication of *paronychia, but is an important predisposing condition* and a condition operating against satisfactory results The *refractory cases of paronychia occur mainly in the* winter months, and it therefore appears probable that *inadequate circulation in the fingers may operate to* some extent in many cases In the aged, in those with Raynaud's phenomenon, and in small children (who have insufficient wit to keep their fingers warm) it may be of considerable importance I have seen 2 cases of gangrene of the finger, and 3 of the great toe, provoked by operations for paronychia It is perhaps insufficiently realised that many cases will recover in due time without any operation, and that in any case a chronic paronychia is better than a gangrenous digit Unless, therefore the first two of these three classes respond to 'Priscol,' it may be wiser to leave them alone If they are operated on they benefit by admission to the warmth of a ward *for two or three days*

Suppurative Arthritis—Bailey (1952) reports 1 case *in a series of subcutaneous infections In 1947 this* clinic had 2 cases from paronychia caused, I believe, *by too extensive reflections of the nail fold* Since then there have been no cases attributable to paronychia The usual cause of this (fortunately rare) complication is a dorsal subcutaneous infection, which, if distal, may closely simulate a paronychia and may later discharge into a nail fold while it is infecting the joint Joints already afflicted with chronic arthritis are particularly susceptible to secondary suppuration from adjacent inflammation, they require special care and an especially conservative approach

Osteitis of Phalanx—There has been no case of bony disease secondary to paronychia in the last five years Paronychia and bony disease may coexist as twin *complications of pulp-space infection* in very rare cases

Stiffness of Joint—Some digital infections produce a sympathetic effusion into the adjacent interphalangeal joint If the suppuration heals rapidly, the effusion may prolong incapacity If the lesion is slow to heal, the *effusion has usually disappeared before the patient* returns to work This condition must obviously be *related to the complication of suppurative arthritis,* but both are more commonly associated with dorsal *subcutaneous and hair-follicle infections*

Strictly speaking, therefore, there should be no complications of paronychia, *though it is important* to discuss the foregoing conditions, if only to dismiss them

CAUSES OF DELAYED HEALING

In a clinic where unsupervised house surgeons, as well as a junior casualty officer, are responsible for many of the operations, some of those cases which fail to h promptly must be attributed to faulty surgery Th particularly so in the surgery of paronychia, bec if it is decided to remove a nail, failure to remove t *amount of nail decided on* prolongs the healing ti Bailey (1952) remarked that the original advice gi in 1948 (to remove only that portion of the nail i by infection) had been superseded by a decision to rem the whole width of the base at least, and there i doubt that, if no incision is made, this change of pol is sound Small pieces of nail inadvertently left behi or cut edges covered by the nail fold, are a comm cause of persistent discharge and further spread o infection

Where incision into the nail flap is indicated, faul siting gives bad results If it is intended to drain a sulcus, the incision should lead down to it unerrin Meticulous precision in operating brings its ow rewards

Pilcher et al (1948) have already emphasised th error of wholesale removal of adherent and unaffecte nail, and their influence has spread so widely that o can say theirs has become the accepted method of treatment *Nevertheless one occasionally still sees* cas where a whole nail has been unnecessarily removed an *a granulating ulcer of the nail bed results* The avul of a normal, or mainly normal, nail almost inevitabl means at least eight days' incapacity

ASSESSMENT OF RESULTS

Bailey's (1952) review assesses the cases in his clin from the day of onset to the day of discharge, and h maintains that this is the most reliable method of estimating the length of industrial incapacity At a teachin centre it is regarded as part of their own responsibility to get the cases in early Nevertheless all clinics have to acknowledge that some of their cases attend much later than is good for them, and all clinics should endeavour to keep the *proportion* as low as possible This clinic often finds that delay in attendance is associated with delay in giving up work, and that many a patient regards *being operated on* for a septic hand (rather than contracting a septic hand) as the cause of his incapacity It seems, too, from Bailey's figures, that the average period of delay is considerably less in London than in this area, though it must be repeated that he discards all cases with delay of over a fortnight In the series about to be cited the average delay was 7 6 days, including 6 cases in which it was *two* or three week In this area patients are astonishingly vague in their ideas about *how long their trouble has been going on* Further, in paronychia the period of delay is no measure of the anatomical situation, and *only in the broadest sense* a measure of the bacteriological situation Under present conditions patients who *attend one day may be referred* for operation to the next, a few patients benefit by twenty four hours' delay, and one or *two may be under treatment* for two or three days before it is decided (usually by someone else) *that operation is indicated* For all these reasons it has been considered profitable to report results in *two ways* by assessing the *period of incapacity* from the day of first attendance, and by assessing the postoperative period of incapacity in addition Othe principles adopted in calculating results have already been set out in a report on pulp space infection (Lowden 195

Conditions of work, both for patients and for doctors vary so much from one part of the country to anoth that I place very little store on comparisons between one clinic and another The *only reliable evidence* that one's routine of treatment is successful is a comparison with *one's own results in previous years* Seasonal variations in incidence and response to treatment make it advisable that *these results should be assessed again* a corresponding season in previous years, or against othe glomerular tufts was slightly swollen, but the elium lining the proximal convoluted tubules was ore affected than the rest. The cells showed cloudy ling, and in some there was nuclear degeneration. David Trevan, of the Wellcome Research Laboras, reported that there was nothing to suggest damage olymyxin E.

3 children there were rises of temperature up to F, considered to have been caused by the antibiotic, 6 other children had pyrexia reaching 99·8°F which ided while polymyxin E was still being administered, was probably not attributable to the antibiotic. Mild l reactions at the sites of injection occurred in 7 dren. In 6 of them the dosage had been relatively e—i.e., 150,000–250,000 units—but the reactions ed little discomfort, never being so severe or so istent as those due to the earlier polymyxin B. Of 7 adults 2 developed slight pyrexia, and only 1 had ht local reactions, although all felt some pain at the ction site lasting a few hours. Such reactions seem lepend chiefly on the size of the dose injected.

ive adults complained of irritation and flushing of the or trunk, and some dizziness when walking. Rashes eloped in 2 children on long courses; in 1 of these a nsient urticaria of the face and trunk appeared on the h day and disappeared while treatment was still being en, and in another, who had previously had papular icaria, transient lesions typical of this condition eloped on the eighth day.

he side-effects after intrathecal injection have been y discussed elsewhere (Swift and Bushby 1951). art from pleocytosis and mild signs of meningeal tation with the higher doses there were no reactions.

COMPARISON OF POLYMYXINS B AND E

ntil recently we had treated only 1 patient, an infant, h the purer polymyxin B (Pfizer), and in this patient side-effects were very like those seen in the children eiving the less pure British product. Now we have n able to compare the side-effects of polymyxin B izer) with those of polymyxin E by treating 6 adults h a three-day course of the American product, and a ek later giving them a similar course of polymyxin E. ree patients were given the polymyxin B as received m America, and 3 were given it after further purificaon by a crystallisation method (Wilkinson 1949). The age was 250,000 units four-hourly intramuscularly. 2 men of the second group the dose of polymyxin E s raised to 500,000 units and further increased to 00,000 units for the last three doses of their courses.

n every patient pain at the injection site was less with ymyxin E than with polymyxin B, even when the e of polymyxin E was twice that of polymyxin B, t not when it was four times as great. Similarly, uration at the site of injection was considerably less d of shorter duration with polymyxin E, except haps when compared with the more highly purified ymyxin B. Pyrexia and malaise occurred with polyxin B, whether purified or unpurified, but with lymyxin E only when the fourfold dosage was given. her subjective sensations occurred with similar quency with either drug.

ince all the patients in this group had infections of urinary tract, there was some proteinuria before atment but it was not obviously increased during or mediately after treatment, and no cellular casts were ssed.

A child was also treated with both polymyxins, the lymyxin B (Pfizer) being given during a course of atment with polymyxin E. The polymyxin E proced only very slight induration at the injection site, ereas definite induration and erythema occurred th polymyxin B.

INCIDENCE OF TOXIC REACTIONS

Polymyxin	No. of patients treated	No. of patients showing renal damage	No. of patients with local reactions	No. of patients with pyrexia	No. of patients with rashes
A	27	26	0	7	0
B (W.R.L.)	24	0	19	18	0
B (Pfizer)	8	0	6	3	0
E	53	0	8	4	2

DISCUSSION

The incidence of side-effects following intramuscular injection are summarised in the accompanying table, the subjective effects being omitted because so many of the patients were infants. There are striking differences between the side-effects of these antibiotics: polymyxin A produces renal damage but little or no reaction at the site of injection, whereas polymyxins B and E cause variable reactions at the injection site but no proteinuria. Polymyxins B and E produced paræsthesiæ in some patients; but, since only children were treated with polymyxin A, it is not known whether this antibiotic also produces these side-effects. The early samples of polymyxin B almost invariably caused malaise with pyrexia, but this has been much less with the more recent and purer polymyxin B.

Polymyxin A is apparently closely related to polymyxin D, for this antibiotic also produced proteinuria (Schoenbach et al. 1948), and polymyxin C, which has never been given to man, causes renal damage in animals. The polymyxins may therefore be divided into two groups according to their toxic effects: (1) polymyxins A, C, and D; and (2) polymyxins B and E.

Their toxic differences are interesting in view of their indistinguishable antibacterial activities, and may be explained by the differences in their molecular size and structure. Other polypeptides cause inflammation, and Spector (1951) found that peptides of about five amino-acid chain-length were not precipitated by ammonium sulphate, and caused only a mild reaction when injected, whereas peptides of 8–14 amino-acid chain-length were salted out by 75% saturation with ammonium sulphate, and caused more severe reactions. Polymyxin A appears to be closely related to the shorter chain-length peptides not only in producing insignificant local reactions but also in not being precipitated by ammonium sulphate. Polymyxin B resembles the longer peptides in causing a more intense inflammation, and being precipitated by 70% saturation with ammonium sulphate. Polymyxin E lies between polymyxins A and B, requiring 80% saturation to precipitate it.

Spector's observations offer an explanation for the differences in the local reactions of the polymyxins, and accordingly polymyxin A should have the smallest and polymyxin B the largest molecule. Bell et al. (1949) from osmometrical measurements calculated the molecular weights of polymyxins A and B to be 1293 and 1150 respectively, and Short (1948), calculating from the phenyl-alanine and threonine content, found the molecular weight of polymyxin B to be 2500.

Spector considers that peptides play a major part in the inflammation caused by burns and bacterial infections, and the similarity between the properties of these peptides and those of the polymyxins offers an explanation for the anomalous fact that the polymyxins are non-toxic to leucocytes yet cause inflammation when injected (Brownlee et al. 1952). The inflammation is not due to direct damage of the tissues but to the fact that the antibiotics behave as peptides derived from damaged tissue.

Differences in molecular weight and shape may also explain the differences in renal toxicity. Experiments on animals show that the damage to the kidneys is

A HÆMORRHAGIC STATE RESEMBLING HÆMOPHILIA

J C F POOLE
M A., B M Oxfd

REGISTRAR, DIVISION OF LABORATORIES, RADCLIFFE INFIRMARY, OXFORD

THE diagnosis of hæmophilia *depends on a family* history showing a sex-linked recessive inheritance, on clinical evidence, and on certain laboratory findings But, because of the high mutation-rate and the high death-rate among young hæmophilics, the family history is often absent or inconclusive Moreover, the clinical features are merely those associated with defective blood coagulation, and are not specific for hæmophilia Consequently, the diagnosis often rests entirely on the laboratory findings

Merskey (1950) studied the laboratory diagnosis of hæmophilia in some detail, and he has shown that the most satisfactory laboratory test is the demonstration that the patient's plasma does not correct the clotting defect of the plasma of a " known hæmophilic "—that is a patient in whom the required genetic, clinical, and laboratory criteria are fulfilled Small amounts of normal plasma and of the patient's plasma are added to citrated plasma from the known hæmophilic, and the clotting-times after recalcification are recorded Very small proportions of normal plasma will shorten the calcium clotting-time of hæmophilic plasma almost to normal *If similar proportions of the patient's plasma* fail to do so, he presumably has hæmophilia This test has the advantage of being independent of the nature of the defect in hæmophilia, it simply shows that two patients have the same deficiency The purpose of this article is to describe a case in which the usual laboratory findings supported a diagnosis of hæmophilia, but in which the patient's plasma corrected, and was corrected by, the plasma of other known hæmophilics

CASE-REPORT

N J is a five year old boy in whom a tendency to excessive bleeding has been observed since the age of 3 months He bruises very easily, and his ankles and knees have been swollen ever since he started to walk There is no convincing family history, but his mother was one of the possible hæmophilic carriers who were found by Merskey and Macfarlane (1951) to have an unusually high prothrombin consumption index (37%)

His admission to hospital with severe epistaxis and hæmorrhage into the muscles of the thigh provided an opportunity to study his condition more fully than had been done before His bleeding time, and the tourniquet test, platelet count, and one stage prothrombin time were normal The whole blood clotting time was 52 minutes (Lee and White) and 10½ minutes (Dale and Laidlaw) The prothrombin consumption index was 150% His plasma did not progressively lengthen the clotting time of normal plasma, so it was presumed *that no anticoagulant was present* The results of mixing his plasma in different proportions with the plasma of 3 undoubted hæmophilics is shown in the accompanying table

CLOTTING TIMES OF RECALCIFIED MIXTURES OF THE CITRATED PLASMA OF THE PATIENT N J AND 3 UNDOUBTED HÆMOPHILICS J D, A N, AND F N

0 1 ml of	Clotting time (min) after adding 0 1 ml of plasma from			
	N J	J D	A N	F N
Normal saline	40	20	17	22
1 100 normal plasma	6½	4½	4	3¼
1 100 N J 's plasma	—	4½	8	4¾
1 100 J D 's plasma	6¾	—	16¾	21
1 100 A N 's plasma	4½	16	—	19
1 100 F N 's plasma	5½	16	14½	—

DISCUSSION

The discovery of this case raises a serious difficult the definition of hæmophilia By the usual criter the boy would be confidently classified as a hæmoph But if we accept him as having hæmophilia, then we postulate mutually correcting subgroups of hæmoph and abandon the idea of excluding hæmophilia demonstrating correction of a known hæmophil plasma However, among the considerable numb patients studied by Merskey no instance was found two supposedly hæmophilic plasma samples correct one another Merskey's series included J D and A 2 of the 3 patients whose plasma is shown here to corr and be corrected by N J 's plasma, clearly, therefo it is N J who is anomalous

The clotting defect in N J was subsequently inves gated more fully by Biggs et al (1952), and other pati with a similar defect have been found Cases of th type have been shown to be deficient in a factor pre both in normal plasma and in the plasma of patie belonging to the group which includes J D, A N, a F N Furthermore, N J and the other patients resembl him are not deficient in antihæmophilic globulin Th these two hæmorrhagic disorders, similar in their clinic features and in most laboratory findings, are in realit distinct from the point of view of their coagulati defects Patients like N J seem to be comparativ rare, and it is therefore suggested that the term hæm philia should be restricted to the larger group in wh plasma samples fail to correct each other, and wh *evidently includes the large majority of cases* hither classified as hæmophilia N J and other patients wit his defect should be regarded as having a different dise for which Biggs et al (1952) suggest the name " Christma disease " after the name of the first patient they examin in detail

RETURN OF LIVER FUNCTION TESTS TO NORMAL AFTER RELIEF OF OBSTRUCTION IN CHRONIC BILIARY CIRRHOSIS

J E RICHARDSON
M S Lond, F R C S

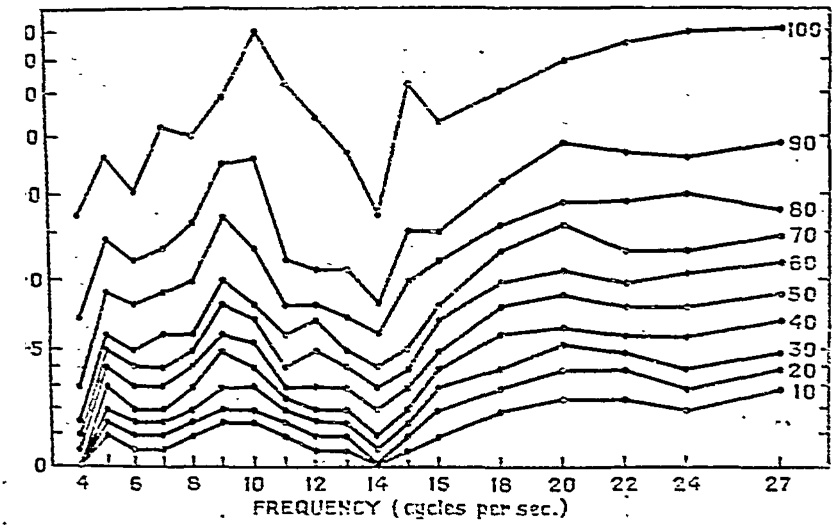
ASSISTANT DIRECTOR, SURGICAL UNIT, LONDON HOSPITAL

THE opportunity of following a patient with bilia obstruction for a reasonable length of time before a after operation seldom arises The interest of the pre *case lies in the serial liver function tests* (see table) I view of the severity of the liver damage the restorati of function following the relief of obstruction was s prising, especially since the patient was aged at least

The patient (record no 3647/48) is well known at the Lond Hospital She was born in Russia about 1893 Her exact a is uncertain because all her papers were lost when she cam England in 1900 She was married in 1927 and has two child who are now grown up and married Her husband die cancer in 1936, and since then she has lived with a niece

Her first visit to the London Hospital was in 1920, wh she underwent hysterectomy for fibroids and a leiomyosarc was found In 1937 she was admitted with an appen abscess In 1945 she attended the gynæcological depart with a pelvic tumour which was thought to be possibly metastasis from her leiomyosarcoma Since she refus operation she was given intensive deep X ray therapy (34

In December, 1945, six months after the conclusion of X ray therapy, the first symptom developed which co possibly be ascribed to the biliary tract She had a seve attack of vomiting, which was diagnosed by her doctor gastritis In June and October, 1946, there were furt attacks of nausea and vomiting During the second att



. 1—Distribution curves of activity from 4 to 27 cycles per sec. for left precentral transverse ·area in 100 cases, independent of sex. Numerals attached to curves denote centiles.

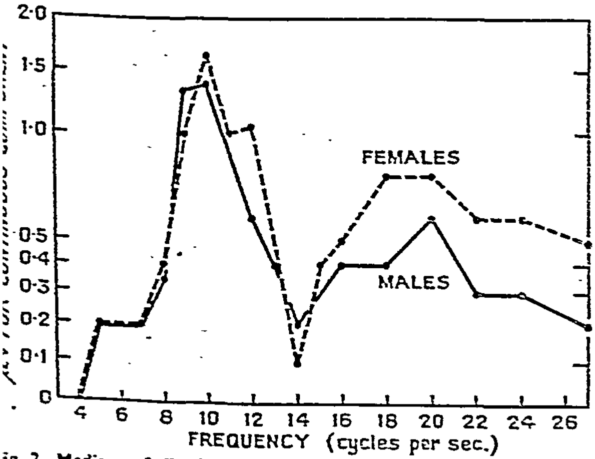
om these areas in each person were taken by standard chniques and fed simultaneously into the wave-analyser. ie instrument was set to write out the average of five ccessive 10-sec. epochs of analysis.

This period of 50 sec. has been used throughout this ries; choice of this period was based on the consideration of the ratio of variability within the individual to constancy from one individual to another. This epoch n be shown to be a reasonable compromise between, the one hand, extreme fluctuation in the individual ie to short period and transient changes and, on the her, masking of broad individual characteristics.

The over-all sensitivity of the instrument was such iat, at the standard setting, a continuous signal of 2μV any of the frequencies in the range led to a write-out ight of 1 cm., and this condition was repeatable to ithin ±10% of any setting at any level.

Voltage/time discontinuity presented without non-nearity or the introduction of spurious harmonics up 100 times this level, though it was usual to use creased or decreased sensitivity settings of the apparatus here necessary. This setting was determined by choosing satisfactory visual level of record in the primary trace, in-to-gain cross-check accuracy being included in the er-all figure of ±10%. Part of the instrumentation has en described (Ellis 1950).

The examination took place in a quietened half-dark om. The patient's eyes were open for 10 sec. during ch 50-sec. period. Analysed frequencies below 4 cycles per sec. were excluded from this study because, in this range, artefacts could not be differentiated from the cortical rhythms with any degree of certainty. The upper end of the spectrum used was fixed at 27 cycles per sec. after an investigation into the frequency distribution of the electromyogram had shown that muscle potentials influenced the analysed result above that frequency.



ig. 2—Medians of distribution of activity from right occipital area for men and for women.

The write-out height of each frequency for each area for these one hundred cases was measured in centimetres; measurement error at all levels was not greater than ±0·05 cm. This measurement was next corrected so that a standard gain setting applied for any one area; this correction was necessary for purposes of comparison and did not introduce any error into the result. The amplitude scale on the ordinate was further corrected by a factor in the form log $(x+0{\cdot}2)$, which is a near approximation to the integral of the summed error of ±10% ±0·05 cm. together with normalisation of the distribution; the same factor has been applied to the statistical procedures used. The corrected measurements in centimetres were plotted, frequency by frequency, against amplitude in the form of dot distribution diagrams. These diagrams were used to check the adequacy or inadequacy of the recording level for the particular area investigated.

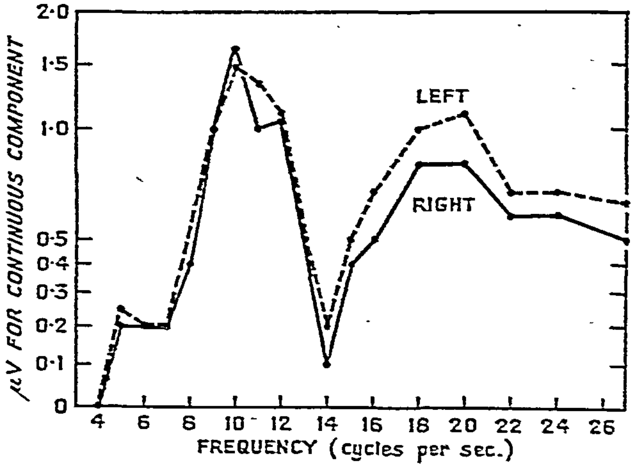


Fig. 3—Medians of distribution of activity from right and left occipital areas for women.

Distribution curves derived from the basic plot show the centile levels from 10 to 100 (fig. 1). The values below the 5th and above the 95th centile are controlled by a small number of people. These values show such a high degree of scatter that their exclusion is justified, particularly since the remaining 90% of the population can be adequately represented by the median; for this reason the median has been used in the illustrations that follow.

RESULTS

Sex.—Fig. 2 shows the results obtained for men and women in the right occipital areas. In the range of frequencies from 15 to 27 cycles per sec. the activity is of a significantly higher amplitude for women than for men. The curves also differ in symmetry over the alpha range, in that the curve for men is skewed, whereas that for

The Mechanisms of Disease

A Study of the Autonomic Nervous System, the Endocrine System and the Electrolytes in their Relation to Clinical Medicine JOSEPH STAMBUL, M D chief cardiovascular dept, Albert Einstein Medical Center (Eastern Division), cardiologist, Deborah Sanatorium New York Froben Press 1952 Pp 746 $15

IN Augustine Birrell's *Obiter Dicta* we read that Borrow's *The Bible in Spain* gained admission to the narrowly selected reading-matter of the Victorian Sabbath by virtue of its 'dear deluding title' This is partly relevant to the volume under review, in that the title is deluding, and the book is dear The practitioner or teacher of medicine to whom the book is commended in the foreword would we believe expect an attempt to explain disease processes in terms of generally accepted physiology and pathology, but Dr Stambul offers something very different

His central theme is that our preoccupation with the physiology and pathology of organs has blinded us to the importance of cell biology disease processes he thinks, can be best understood in terms of alterations in cell permeability, brought about by autonomic nervous impulses by hormones or by changes in electrolyte concentration in the surrounding fluids With this hypothesis in mind, he embarked on a long search of the literature whose results are presented in this massive volume Many of his conclusions are surprising for instance 'bacterial toxins affect tissue cells by way of the autonomic nerve fibres that supply these cells" 'the degree of effectiveness of a diuretic depends upon the ease which which it ionises calcium , "the hormone of the pancreas insulin influences the deposition of glucose in the muscle cells by counteracting the membrane semipermeability and permitting the glucose from the surroundings to enter the cells." These are matters of theory but they are less astonishing than his assertion that adrenal cortical hormone therapy "should be instituted early in acute infections in order to prevent irreparable damage to the tissues caused by pathogenic micro organisms"

The clarity of the writing makes apparent the highly speculative nature of the contents

Saving Children from Delinquency

D H STOTT, PH D research fellow Institute of Education University of Bristol London University of London Press 1952 Pp 266 12s 6d

IT is an unfortunate feature of human psychosymbolism that rational proposals for the prevention of crime are less effective in exciting our public, our press and our judges than sadistic methods of punishing it Dr Stott's Carnegie study on *Delinquency and Human Nature* was a humane and hard-headed study of child criminals praiseworthy for both its good sense and its psychological eclecticism His new book is of wider scope in suggesting remedies The commonest cause of delinquency in his view, is desperation. child crime is essentially an explosive disorder. The Bench or some of its members at least are likely to welcome the book for it provides a background to every decision which has to be made in a case of childhood delinquency and gives a remarkably accurate idea of the sort of help in elucidation and treatment which can be expected from sensible psychiatry The roots of the desperation which Dr Stott cites lie deeper in our culture pattern than his non-anthropological approach seems to suggest, but the programme of prevention and treatment he outlines is practicable if our society is culturally able to accept it

There have been other good books of this kind, but few better Dr Stott writes persuasively out of a very wide personal experience

Physical Diagnosis

HARRY WALKER M D, F A C P, professor of clinical medicine, Medical College of Virginia London Henry Kimpton 1952 Pp 461 60s

TEXTBOOK instruction on methods of physical examination is never an easy task, for these are essentially practical arts to be taught at the bedside. In this volume one of the main aids to a clear understanding of clinical methods—namely, the use of illustrations and diagrams—is disappointing Of the 126 illustrations, som be of little importance and inferior quality The tions of physical signs are also often brief and unin tive Some 30 chapters cover all the principal d and there are introductory chapters dealing wi things as habitus body-temperature, speech, gai inspection and palpation There is an exceedin short account of methods of psychiatric examin

Scoliosis

Pathology, Etiology, and Treatment SAMUEL KL M D, assistant orthopædic surgeon, Hospital fo Diseases, New York City London Baillière T & Cox 1951 Pp 286 37s 6d

AN orthodox review of the anatomy of the sp the different types of lateral curvature leads th to conclude that the ætiology of idiopathic s remains an unilluminated page but he is imp with the evidence implicating asymmetrical distur of vertebral epiphyseal growth in some cases a foresees future treatment of established curv surgical inhibition of growth on the convex side, by stapling or by other means He does not m how greatly the prognosis differs in the different of curvature and attaches little importance to the ex measurement of curve angles preferring the s visual comparison of serial radiographs Neither he share current pessimism on the value of non-op management in structural scoliosis, exercises in ticular are described in detail, though he does not s dogmatically that these can undo rotation, and does refer to the specific derotating exercises used by experienced physiotherapists There is a full acc of methods of forcible correction plaster technique apparatus, and, though Dr Kleinberg is conserv in advising operation his success in obtaining f with preserved beef bone makes one wonder whe "bone bank" of refrigerated homogenous bone is necessary

Surgical Papers

WILLIAM STEWART HALSTED, late professor of sur Johns Hopkins University Editor WALTER C BURK *Baltimore Johns Hopkins Press London Ox University Press* 1952 Two vols Pp 586 and £10

A PART of the centenary celebrations, held last at Johns Hopkins Medical School of W S Halsted's birth is the re-issue of his collected writings Vo of these contains his papers on surgical techni conduction anæsthesia, intestinal surgery with spe regard to methods of anastomosis, the surgery of t blood-vessels, and some shorter contributions on cellaneous subjects Vol II contains his work on c of the breast, the surgery of the thyroid, parathy and thymus glands, the surgery of the bile ducts pancreas some miscellaneous papers, and a bibliograph

Halsted's papers are models of what scientific pap should be—lucid, well documented, and bearing evide of the most intensive work and study in their preparati Apart from their presentation they contain a mas original observations which are still pertinent, many these are still not widely known The general princip enunciated are continually illustrated in his writings they are the same now as they were in his day cannot be reminded too often of the importance of g handling of the tissues, exact hæmostasis, and t sacrifice of theatrical operating to care and thorough His insistence on the importance of applying the resour of the laboratory and the teachings of surgical patholo to clinical problems is an object-lesson The pape vol I are perhaps of less interest than those in vol except for the remarks on surgical technique and ligat of the large arteries Much of the elaborate work intestinal suture is of historical interest only, and wrote very little on his classical contribution to anæsthesia Vol II contains his wonderful pap cancer of the breast which could be read with p by any surgeon who operates on this condition nowaday The paper on the operative story of goitre finishing details of the Halsted technique, beautifully illustrate is absorbingly interesting His remarks on the train of the surgeon are as apposite as they were in 1904

OOD-PYRUVATE LEVELS IN SUBACUTE COMBINED DEGENERATION OF CORD

EFFECT OF VITAMIN B_{12} THERAPY

C. J. EARL
M.D. Lond., M.R.C.P.
LECTURER IN CHEMICAL PATHOLOGY

M. F. S. EL HAWARY

R. H. S. THOMPSON
M.A., D.M. Oxfd
OFESSOR OF CHEMICAL PATHOLOGY IN THE UNIVERSITY OF LONDON

G. R. WEBSTER
M.A., B.M. Oxfd
JUNIOR LECTURER IN CHEMICAL PATHOLOGY

GUY'S HOSPITAL MEDICAL SCHOOL, LONDON

IN the course of a study of pyruvate metabolism in eripheral neuritis and myelitis we have had the pportunity of investigating three untreated cases of bacute combined degeneration of the cord, and of bserving the effect of treatment with vitamin B_{12} n the blood-pyruvate levels in these cases. In view f the difficulty of obtaining cases of this condition at have received no treatment with either liver con-entrates or vitamin B_{12} we describe here the results btained.

METHOD

On admission to hospital blood-pyruvate levels were easured by the method of Friedemann and Haugen 1943) in the fasting state and at 60 and 90 min. after loading dose of glucose (Williams et al. 1943). The ean levels which we have obtained in healthy people nder these conditions are 0·76 ± 0·18 mg. of pyruvic cid per 100 ml. of blood in the fasting state, and ·92 ± 0·17 and 0·94 ± 0·20 mg. per 100 ml. at 60 and 0 min. respectively (Joiner et al. 1950). The test was epeated after a course of parenteral therapy with itamin B_{12}.

CASE-RECORDS

Case 1.—A married woman, aged 28, admitted to hospital December, 1950, with two years' history suggesting ernicious anæmia, had had no effective treatment. Two eeks before admission there had been a sudden onset and apid progression of paræsthesiæ and loss of feeling and ower in both feet and legs. Just before admission the aræsthesiæ spread to the hands.

On examination the patient was pale, had a smooth tongue. nd could not walk. Muscular tone in the legs was increased, oördination was grossly impaired, and there was some weak-ess of hip flexion. Light touch and position sense were npaired in both legs. Deep reflexes were increased, and oth plantar responses were extensor.

Investigations showed histamine-fast achlorhydria. Hb 9%, red cells 2,300,000 per c.mm., mean cell diameter (M.C.D.) ·6 µ, conspicuous anisocytosis and poikilocytosis, and ternal marrow typical of pernicious anæmia.

Treatment with vitamin B_{12} 50 µg. three times a week was tarted on Jan. 9, 1951. No other vitamin therapy was given. his produced a reticulocyte response and by March 1, 1951, he blood picture was normal. Improvement in the neurological ondition was slower, but by March 16 the patient could alk unaided, although the plantar responses remained eakly extensor.

Pyruvate metabolism was as follows:

Date	Blood-pyruvic acid (mg. per 100 ml.)		
	Fasting	*90 min. after glucose*	
an. 8 1951	0·55	1·70	before vitamin B_{12} therapy
,, 22 ,,	0·78	1·46	14 days after start of vitamin therapy
larch 15 ,,	0·41	1·02	2 months ,, ,, ,, ,, ,,
une 29 ,,	0·83	1·10	6 ,, ,, ,, ,, ,, ,,

Case 2.—A man, aged 60, was admitted to hospital in larch, 1952, with six months' history of numbness of the ands and feet.

On examination his skin was pale yellow, his tongue smooth, and his gait grossly ataxic. There was weakness of the hand muscles and of hip flexion, with impairment of sense of position and of vibration in the arms and legs, and of superficial sensation below the knees. The calves were tender, and the knee and ankle jerks were absent.

Investigations showed Hb 76%, red cells 3,400,000 per c.mm., M.C.D. 7·9 µ, with anisocytosis and poikilocytosis. There was a histamine-fast achlorhydria.

Treatment with vitamin B_{12} 100 µg. twice weekly was started on May 31. No other vitamin therapy was given. The blood picture was normal on July 15, and there was a fairly rapid improvement in walking and physical signs.

Pyruvate metabolism was as follows:

Date	Blood-pyruvic acid (mg. per 100 ml.)		
	Fasting	*90 min. after glucose*	
May 30 1952	0·75	2·60	before vitamin B_{12} therapy
June 12 ,,	0·87	1·26	13 days after start of vitamin therapy

Case 3.—A married woman, aged 57, admitted to St. Bartholomew's Hospital under Dr. J. W. Aldren Turner in June, 1952, had noticed numbness of the finger-tips and of the feet for eight months, and had had difficulty in picking up small objects. For six months before admission her gait had been unsteady.

On examination power was normal, but muscle tone in the legs was slightly increased, and coördination was slightly impaired. Knee-jerks were feeble, ankle-jerks absent, and plantar responses doubtfully extensor. Superficial sensation was impaired below the knees, vibration sense absent in the lower limbs, and position sense impaired in the toes.

Investigations showed Hb 92%, red cells 4,350,000 per c.mm., colour-index 1·07, mean corpuscular volume 92 c.µ, histamine-fast achlorhydria, and sternal marrow like that of subacute combined degeneration.

Treatment with vitamin B_{12} 40 µg. on alternate days was started on July 18. No other vitamin therapy was given. No change in physical signs occurred within fourteen days, but the patient thought that the numbness was less. Two months later there had been a progressive slow improvement in her condition.

Pyruvate metabolism was as follows:

Date	Blood-pyruvic acid (mg. per 100 ml.)		
	Fasting	*90 min. after glucose*	
June 27 1952	0·83	1·77	before vitamin B_{12} therapy
July 15 ,,	0·81	0·91	17 days after start of vitamin therapy

COMMENTS

Since, so far as we are aware, no evidence of any clear-cut relationship between pyruvate metabolism and vitamin B_{12} has been described, and since the method of Friedemann and Haugen (1943) is not completely specific for pyruvic acid but also estimates other keto-acids to some extent, we thought it advisable in cases 2 and 3 to separate the blood keto-acids by paper chromatography and so to obtain individual estimates for the pyruvic and α-ketoglutaric acids normally found in human blood (El Hawary and Thompson 1953). The results obtained are shown in the accompanying table. The values of 1·29 and 1·15 mg. of pyruvic acid per 100 ml. of blood for the 90 min. specimens obtained before treatment are significantly higher than the corresponding levels of the separated pyruvic acid found in normal people by this technique. It will be seen also that the 90 min. samples after vitamin B_{12} therapy are only 0·37 and 0·39 mg. per 100 ml. respectively in these two cases—i.e., within the normal range.

The values for α-ketoglutaric acid are not raised and are unaffected by treatment with vitamin B_{12}. The

Epidemiology in Reverse

When KOCH announced his famous postulates the ætiological agents of most infectious diseases were unknown Now that these have been satisfactorily established for nearly all infectious diseases, a new situation has arisen viruses are being discovered without diseases to match To the pure bacteriologist this *may seem natural enough, for the great majority* of bacteria are harmless or even beneficial saprophytes and the pathogen is very much the exception But those who work with viruses have learnt to recognise them by their ability to produce disease, and a scientist who isolates a new virus without knowing the disease it causes is looked at askance by his colleagues Let him beware, however, of the temptation to short-circuit KOCH's postulates, either in letter or in spirit, in his anxiety to find a parent disease for his foundling

A good example of this epidemiology in reverse comes from the Coxsackie viruses During investigations on poliomyelitis, DALLDORF and SICKLES[1] isolated from the stools of two children with paralysis a virus which in suckling mice caused fatal disease with widespread muscular necrosis They proposed the name Coxsackie virus for this new agent, but it was not immediately obvious what disease it caused Some 15–20 serological varieties of Coxsackie virus have now been recognised and they have been accused of causing many diseases It seems likely that they are responsible for epidemic pleurodynia[2] (Bornholm disease), herpangina,[3] and certain non-specific summer febrile disorders[4] Their distribution is very similar to that of poliomyelitis viruses *and their relation to* this disease is intriguing There is still no evidence that they cause poliomyelitis-like diseases alone, but some varieties may convert a subclinical attack of poliomyelitis into a paralytic one Coxsackie viruses seem to be extraordinarily widespread, they have been recovered in large numbers from the four corners of the earth, and their association with human disease may be the exception rather than the rule

Epidemiology in reverse has also been encountered in East Africa A group of workers in Entebbe, Uganda, while looking for reservoirs of yellow fever, inoculated various materials into mice and recovered a number of curious viruses This led to a search for the corresponding diseases Dr G W A DICK, who for some years was a prominent member of the team, described some of the results in a lecture to the Royal Society of Tropical Medicine and Hygiene on Dec 11 Two of the agents discovered by these workers in East Africa—Bwamba fever[5] and West Nile[6] viruses—were isolated from the sera of patients with febrile disease, although the exact relation of these viruses to human disease is still not clear Most of the other viruses—for example, Uganda S[7]—were isolated by inoculating suspensions of mosquitoes into mice, but the possibility that some of these injections activated latent mouse viruses has not b excluded with certainty Attempts were mad estimate the importance of these viruses to di in man by antibody surveys of human sera,[8] bu interpretation of such tests is not always si The presence of virus neutralising substances i small proportion of human sera is of itself evidence (as KOCH would have agreed) of pre infection with that virus Even the demonstrat of a rise of antibody to a virus during a prim illness must be interpreted with caution T although a herpetic may show a rise in antibody herpes-simplex virus during an ordinary bact pneumonia, no one would infer from this that herpes-simplex virus is the cause of lobar pneum Nevertheless, inferences of this sort are all common

Dr DICK is aware of these difficulties, he arg that these new viruses deserve study since they m at any time break loose and cause serious dis such as occurred in the recent Australian epidemic Murray Valley encephalitis[9] His remarks should *taken seriously, although, of course, the same* warn applies in greater or lesser degree to all bacteria a viruses Even the harmless staphylococcus on th bacteriologist's bench may conceivably turn vic and bite the hand that feeds it, and the scient has a duty to the community to estimate these r in the case of any newly discovered potential pathog *He cannot do this, however, until he has* a sou knowledge of its distribution in nature, its path genicity, and its general behaviour in the laborator These fearsome-sounding new viruses are of gr biological interest, but it would be no surprise t learn that many of them are harmless, seek nothing but food, warmth, and comfort from th hosts, anxious not to disturb or to be disturbed living the most luxurious of what LAIDLAW call "borrowed" lives

Topical Application of Histamine Antagonists

THE intrinsic value of remedies designed to relieve subjective symptoms is never easily gauged and uncontrolled trials, however large, may be deceptive Anti-histamine drugs incorporated in various ba are widely used as local applications for the relief of pruritus and itching dermatoses, and they have be reported to bring relief in 60–90% of cases

WALDRIFF et al[10] describe the effect of anti*histamine creams in 277 cases of neurodermatoses* a generally superior to that obtained by the intern administration of these drugs (78% of all patient relieved by topical use, compared to 56% by or administration) About a third of the patient with neurodermatitis were "semipermanently c permanently cured" In this trial eczemato reactions ensued in 4 5% of the cases, and we commonest in patients with denuded, excoriated c weeping dermatoses—for example, some forms c anogenital pruritus and of disseminated neuroderm titis Local application of anti-histamine drugs to ar of mild, dry, circumscribed contact dermatitis ga

esponse to Injection of Adrenaline.—No eosinopenia was ːrved at four or six hours after the injection of 0·4 ml. of)00 adrenaline.

esponse to Restriction of Salt.—On restriction of dietary ium chloride to less than 0·5 g. daily there was prompt mal diminution in output of sodium chloride (fig. 1).

esponse to A.C.T.H.—The patient was kept on a diet of stant sodium, potassium, chloride, and fluid intake. .T.H. prepared in our own laboratory (Cortis-Jones et al. 9) was injected six-hourly in a dose (daily total 50 I.U.) own to stimulate the adrenal glands in a normal adult. e results are shown in fig. 1. There was no evidence of inopenia, retention of salt, or loss of potassium in response A.C.T.H. On the other hand, the output of 17-ketosteroids s significantly increased.

esponse to Cortisone.—The effect of cortisone on circulating inophils and urinary excretion of sodium. potassium, oride, and 17-ketosteroids was studied during the second mission in January, 1951. Cortisone acetate 50 mg. was ected twice daily for ten days. A progressive decrease in inophils followed; there was slight retention of salt; and output of 17-ketosteroids was strikingly diminished . 2).

Effect of Continued Cortisone Therapy.—It was impossible keep the child in hospital and in view of these results it s decided to treat her at home with oral cortisone daily. r progress over the subsequent seven months is shown in . 3. Two weeks after the ten-day course described above, ·5 mg. of cortisone was given daily for ten days. A mild tack of vomiting developed, and cortisone was withheld by e mother. At this time the output of 17-ketosteroids had en to an abnormal level. The dose of cortisone was raised 25 mg. daily for seven weeks. At the end of this course the tput of 17-ketosteroids had fallen to less than 1 mg. in enty-four hours. Clinical examination showed no change the child's appearance since the first admission. Cortisone erapy was discontinued, and her condition remained satis- tory for a month. A severe attack of headache and miting then came on, followed by much weakness for five ys. The output of 17-ketosteroids after the attack was ain abnormally high. Two months after the attack cortisone erapy (50 mg. twice weekly) was resumed. During the rth week of this course a further attack of vomiting came and was followed by extreme prostration and death. fortunately it was difficult to maintain close contact with e patient, and it was impossible to make any observations ring the attacks.

Necropsy revealed a grossly dehydrated child. Pubic hair s present, but no axillary hair. The clitoris was enlarged, t the vagina, uterus, fallopian tubes, and ovaries appeared rmal. The urethra was separated from the vagina. Both adrenals showed considerable cortical hyperplasia (left 13·3 g., right 11·6 g.).

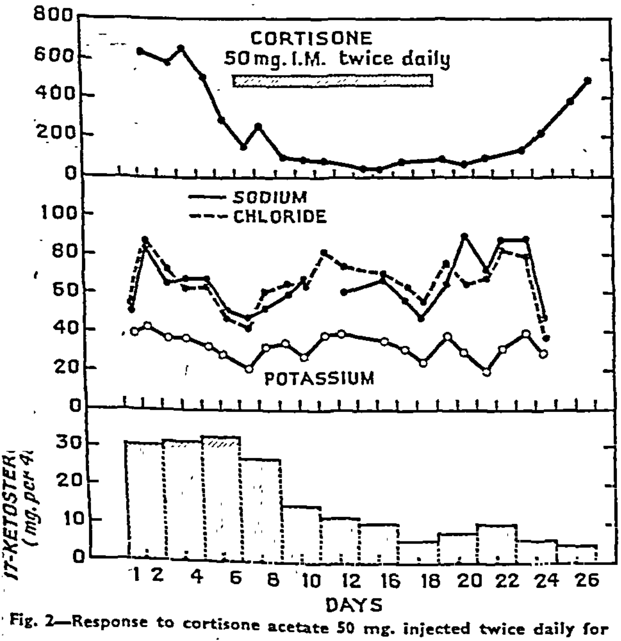

Fig. 2—Response to cortisone acetate 50 mg. injected twice daily for ten days.

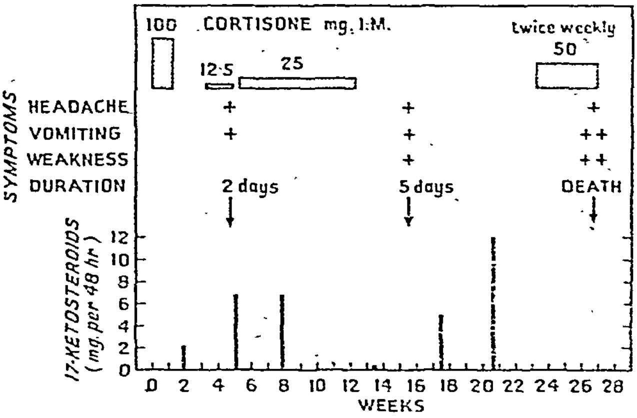

Fig. 3—Response to continuous therapy with cortisone acetate.

DISCUSSION

The clinical diagnosis of adrenal pseudohermaphroditism in this patient was based on the presence of an enlarged clitoris at birth, progressive virilisation with a high 17-ketosteroid excretion, and the advanced state of epiphyseal development. An unusual feature was the presence of separate urethral and vaginal orifices. Wilkins (1950) records only 1 such case, for the usual finding is a urogenital sinus. The degree of normal genital differentiation in this patient suggests that the excessive androgenic stimulus from the adrenals developed later in fœtal life than is usual in such cases.

The natural history of the metabolic disturbance is also unusual, in that there were no symptoms referable to adrenal insufficiency until attacks of vomiting developed between the ages of 2 and 4 years. In view of the child's subsequent progress these attacks were most probably related to adrenal insufficiency. Examination of published reports of 22 fatal cases shows that symptoms of adrenal failure developed within the first month of life in 18, and between the ages of 6 weeks and 7 months in 3 cases; only 1 patient was free from symptoms until the age of $3^1/_2$ years.

The clinical picture of vomiting, dehydration, and collapse that preceded the death of this patient has been described in all the reported cases in which death was due to adrenal failure. The picture is closely similar to that of an addisonian crisis in the adult. As with Addison's disease, a crisis may be precipitated by infection (Thelander 1946) or operation (Allibone et al. 1947), and death may take place despite restoration of the electrolyte balance (Zuelzer and Blum 1949). The biochemical findings have been depletion of sodium and retention of potassium. Few data are available on the blood-sugar levels during a crisis, but severe hypoglycæmia has been reported (White and Sutton 1951). Adrenal failure in the presence of hyperplastic adrenals seems to be very like failure due to destruction of these glands. The published data do not justify the view (Wilkins and Lewis 1948) that this adrenal failure with excessive production of androgen is confined to a lack of salt-retaining hormone. In contrast to this group, most patients with hyperplastic adrenals secreting excessive androgens from before birth undergo progressive virilisation without clinical evidence of adrenal failure. Nevertheless the investigations of Bartter et al. (1951) and Wilkins et al. (1950) show that there is an underlying abnormality of the adrenal cortex common to patients with and without overt adrenal insufficiency.

The case reported here is of particular interest in that studies with A.C.T.H. and cortisone were made when there was no clinical evidence of adrenal failure, and the patient survived a period of very restricted salt intake in the words of the Coalition Government in the British white paper of 1944) that the health of the people was a *responsibility of government*

A hundred years' lag between the expression of a basic principle and its actual application is about average for this country Professor Titmuss attributes the delay in this case to the fact that the present British social services—the Welfare State—had to be built up from below When the old sources of social security—the Church, the parish poor-box, the charity of the lord of the manor—could no longer meet the demands on them, the poor working people began, voluntarily and democratically, to make their own provisions for social security They created, he said, an embryonic Welfare State, resting on the principles of mutual aid In the belief that all should compulsorily stand together to meet the needs of sickness, injury, old age, and unemployment, they built up a vast organisation of friendly societies clubs, and trade unions "The term 'friendly society' is very significant here, positively it expressed the idea—surely a Christian idea—of mutual neighbourly help in the contingencies of industrial, city life, negatively it expressed the working class loathing of a harsh poor-law and authoritarian forms of charity" It was in direct opposition to the doctrine of laisser faire "Every man," John Donne had written centuries before, "is a piece of the Continent, a part of the main any man's death diminishes me, because I am a part of mankind" The working class of the 19th century were not the only ones to experience intuitively this truth there were the great rebels of the humanitarian movements—men and women with a tradition of public service like Lord Shaftesbury, Elizabeth Fry, Octavia Hill Florence Nightingale, and Charles Booth They rebelled, as Professor Titmuss said, "against the excesses of a philosophy of unbridled individualism", and many of their rebellions were successful, because they were based on a passionate desire for social justice They are still with us, the private rebels and reformers, still moved by the same desire and still expressing it in voluntary social service

> "Over 10,000 men and women are now engaged, in a voluntary capacity, in running the present system of hospital boards and hospital management committees under the National Health Service Never before have so many voluntary workers been engaged in constructive work on hospital boards and committees"

The conjunction of two social forces—the working-class ethic of mutual aid, and the educated man's tradition of public service—achieved the social policies of the early years of this century national insurance schemes of sickness benefit, general-practitioner care, unemployment benefit, and workmen's compensation, and the beginnings of school meals, a school medical service, and a maternity and child-welfare service The Boer War, by revealing much physical unfitness among recruits, fostered the revolutionary idea of prevention "It was revolutionary because it spelt publicly sponsored services and a higher income tax"

The second Industrial Revolution—the scientific revolution—aggravated the social problems of the first Children meant poverty and poverty, as always, meant sickness Social services multiplied to meet special needs—"a patchwork," as the Beveridge report said, "of disconnected administrative organs" The second world war taught us still more about basic social needs, and especially the need to get away from a two-standard service—an inferior standard of health care, education, and nutrition for the poorer classes, a higher standard for the better off A civilians' war, we found, must be fought on the principle of "fair shares," and this principle was carried over into the peace and written into the National Health Service, National Insurance, National Assistance, and Family Allowances Acts, and the Education Act In this legislation we can di recognition of the importance of the family a recognition that the costs of unemployment and sick must be a national charge, a greater emphasis prevention, and the backing of scientific medicine the State, so that all may benefit by it The work incomplete, and we have often made mistakes, Professor Titmuss believes that the aims of the Welf State do offer a healthy alternative to either a totalitar State or a system based entirely on materialistic value

INTESTINAL MOVEMENTS

MOVEMENTS of the alimentary canal in man have b studied mostly by radiological techniques, or else by introducing balloons to record pressure changes Both methods have their disadvantages, and neither gives results that are as straightforward as they may seem With balloons changes of pressure due to intestinal movements may be too sluggishly recorded, or if the balloon is so inflated as to distend the walls of the g this may itself initiate movements Code et al[1] at the Mayo Clinic have worked out their own method of recording pressure by means of balloons, but they make it clear that this is inaccurate for contractions recurring more than once in about 5 seconds Contractions of h greater frequency can, however, be recorded by transforming changes of pressure into variations of electric current

Code and his associates agree with earlier workers in describing three types of intestinal movement Type 1 is reflected in low amplitude waves, each lasting seconds, which are very constant for any particular portion of bowel Type-2 waves are of greater amplitude and may last up to 60 seconds In type 3 a change of tonus or "base line," sometimes lasting for minutes, added to waves of type 1 or 2, this 3rd type is seen most commonly in records of the small intestine In patients with ulcerative colitis there may be a further type (type 4) of large single waves, lasting 1–2 minutes, this type seems to be limited to the colon In the small intestine type-1 waves are mainly for "mixing" and type-3 waves for propulsion, type-2 waves are rarely if ever, seen In general the small intestine shows much more continuous activity than is evident in either the stomach or the colon, it is at rest for less than half the twenty four hours, being depressed in sleep when type 3 waves largely disappear

Ingelfinger and Moss[2] have shown that nausea is often associated with generalised contraction of the duodenum, and other investigators have noted duodenal spasm during mental or physical situations which involve distress or pain Many agents reduce or inhibit motility of the duodenum or small intestine one is atropine, while others are such drugs as tetraethylammonium chloride and 'Banthine' It is not, however, so well recognised that transit through the small bowel is also delayed in such conditions as acute bacillary dysentery With obstruction of the small intestine type 3 waves increase, with a gradual disappearance of type 1 ("mixing") waves In observations on an isolated loop of jejunum Jackson[3] found that propulsive waves were most violent when the distal end of the loop was occluded and fluid was introduced into the proximal end Pain however did not seem to be related so closely to the peristaltic waves as to the type of fluid introduced into the loop Thus water or 5% glucose solution caused only slight discomfort, whereas 50% glucose solution caused extremely severe colicky pain referred to the umbilicus—which persisted after peristalsis had ceased in the loop Our knowledge of the sensory innervation of the small intestine is far from complete, but all evidence seem to show that distension is the main—if not the only—stimu

t complications than do early ones (Lowden 1951, ey 1952, and others).

a paronychia two anomalies are at once apparent. ay in seeking treatment bears no relationship to the ent of the lesion and, as a corollary to this, no relation- to the time required to heal the lesion. It is astonish- how quickly an infection in one case can spread round l under a whole nail, floating it away from the nail l, whereas in another case of longer duration it may duce no more than a little discharge from the base or localised pocket of pus in one corner. An analysis this clinic of 50 consecutive cases according to their lay in seeking treatment and their healing-time after ndard operations, did not show any relationship tween the two. The most outstanding extremes re a case with two days' history which took thirty- ur days to heal, and another which had been established r three months and healed on the eighth day. At at time (1948) an analysis of cases treated with nicillin and those treated without showed no significant fferences. In this clinic in four years the average capacity for subcutaneous infections has been reduced y nearly 40%; and for pulp-space infections by 60%, ut for paronychia, until recently, by little more an 6%.

Pilcher's conception (Pilcher et al. 1948) of paronychial fection is that it starts as a subcuticular infection f the nail fold or the lateral sulcus; on this assumption e maintains that an incision into the subcutaneous issue is not only unnecessary but also may delay healing y infecting an area not previously involved. There are, owever, certain theoretical and practical objections o these views. The most practical objection in this linic was that 107 cases treated by Pilcher's conserva- ive operation averaged slightly longer than 116 cases reated by Kanavel's standard operation (Lowden 1952). Moreover, many cases proved at operation to be ot entirely subcuticular infections, and even mainly ubcutaneous infections, with well-defined paronychial pockets and small extensions or none at all under the nail; and a few had discharging sinuses through the nail fold, showing that subcutaneous tissue was most certainly involved. Those with well-defined subcutaneous abscess cavities alongside the nail fold—a type which Bailey (1952) considers rare—occur quite commonly in this clinic. In the last 34 cases at least 10 have been observed. Why some should develop in this direction, and some remain subcuticular, has not so far been determined, though one's impression is that the subcuticular type occurs predominantly in young people and children. However caused, the subcuticular ones produce a rapid spread under the nail, and pus often extends beyond the nail bed, stripping the cuticle from the finger and extending proximally towards the hand. These cases often take a long time to heal, leaving an impetiginous lesion of the finger which outlives the original lesions of the nail bed by many days.

Finally, it is unreasonable to assume that the infection is staphylococcal by the time it is first seen at a hand clinic—at least, not without further consideration. Cultures taken either at operation (if there is no discharge on first attendance) or on sight (if there is) indicate that some of our cases grow gram-negative bacilli or (what is equivalent for practical purposes) penicillin-resistant cocci. This fact, coupled with the fact that much of the administration of penicillin in earlier days was haphazard, might explain the findings that penicillin-treated cases did little better than those without it. For many months in this clinic it was not considered that penicillin therapy in paronychiæ was worth the expense.

If the results of cultures are assessed according to whether the lesion has discharged on the surface, when the culture is taken, or has remained intact, it is seen that, up to now, the penicillin-resistant organisms, when they occur, are nearly all in the former. The intact lesion is still staphylococcal or staphylococcal and streptococcal (table I). Reliance cannot be placed on figures derived from thirty swab reports, but the fact that these organisms do occur in paronychia is significant. The nature of the infecting organism cannot be correlated with the distinction in clinical behaviour described already. Most of the subcuticular lesions, whether discharging or not, remain staphylococcal. On the other hand, one at least of the *Bacterium coli* lesions was localised and subcutaneous. The original lesion is probably staphylococcal and rupture gives an opportunity (not always taken) of infection by gram-negative or other resistant organisms.

TABLE I—BACTERIOLOGICAL FINDINGS IN PARONYCHIA

Bacteria	Unruptured	Ruptured
Penicillin-sensitive :		
Staphylococcus aureus	12	8
Staph. aureus and hæmolytic streptococcus	3	8
Penicillin-resistant :		
Staph. aureus and hæmolytic streptococcus		2
Coliforms		2
Proteus	1	1

All were chloramphenicol sensitive.

RELATIONSHIP WITH PULP-SPACE INFECTION

Bailey (1952) reports 5 cases in which he described extension into the pulp space, though he remarked that they were more probably cases of pulp-space infection which pointed in the nail sulcus, having tracked alongside the phalanx. No doubt this latter process can take place and has taken place in most of the apparently combined lesions. Very rarely however, a pocket of pus in the sulcus is observed beginning to track into the pulp space. Only by very accurate observation can the classification be precise.

The situation is complicated by the fact that the inexperienced may be tempted to remove the nail in late neglected ("bag of pus") pulp-space infections. Fluctuation (an unreliable physical sign in fingers) under the nail may be detected. In these cases the pus tracks between the phalanx and the nail bed, raising nail and nail bed together; removal of the nail in such a case is mischievous (Lowden 1951).

CHRONIC PARONYCHIA

Bailey (1952) draws an arbitrary line at fourteen days and only considers the "acute" cases. It is convenient to have some such standard, but histories of septic hands are notoriously unreliable, and we have established that many long-standing cases present the same clinical features as more "acute" ones, and are cured as swiftly. Many of them, also, grow typical organisms. "Chronic" paronychia, as distinct from "late" paronychia, may more properly be assessed on its clinical appearance. It is better known to the dermatologist than to the surgeon, and, let it be confessed, often better treated by the dermatologist. The lesions are often multiple. The history is measured in weeks or months rather than days—sometimes in years. There is a little cheesy discharge. The nail fold hangs away from the nail, and the surrounding skin may be macerated. If the dermatologist fails to cure it, which is unusual, a cure may be obtained by removing the bases of all affected nails, carefully excising all loose and macerated tags of cuticle from the nail fold, and treating *daily* thereafter with Castellani's paint. The patients should be admitted to hospital because the operation may take a long time, and to operate on both hands at once is incapacitating. All affected nails should be done at one sitting, if possible, for fear of reinfection.

œsophageal-pulse records which they feel can be interpreted as showing the presence and nature of mitral disease Zoob has obtained similar records but is less confident about their interpretation A cautious attitude may be wise These two groups of workers agree that the œsophageal pulse does not actually measure the left auricular pressure, and furthermore the experience of Wynn and his colleagues,[13] who made direct measurements of auricular pressures at operation, suggests that the interpretation of these pressures in mitral disease is far from easy. The status of the "œsophageal piezocardiogram" is still uncertain, and further direct correlation of it with operative findings would be helpful

"FUNCTIONAL END-ARTERIES" IN MUSCLE

ONE of the more tedious occupations pursued by the student of anatomy is the memorisation of the great system of collateral circulations by which the body safeguards its lines of communication Now that aneurysms are out of fashion the meaning of this system often becomes clear only when he sees a coarctation of the aorta or Blalock's operation The surgery of congenital vascular defects often demonstrates the astonishing extent to which these "by-passes" can dilate in response to need For example, in a case of coarctation Clagett[14] ligated the left subclavian artery above its branches and also the first three left intercostal arteries; the hand was pulseless for some time, yet it showed no sign of gangrene

In other situations, however, collateral circulations are not so successful, and some arteries have won notoriety as "functional end-arteries," implying that if they are blocked the central part of their distribution will die or be severely injured by ischæmia Such a result depends on a combination of factors, among which are the rapidity of the blockage, the oxygen needs of the tissue, and the capacity of the collateral vessels to respond If the occlusion of the artery is gradual, the collateral circulation has time to dilate to the best of its capacity and the tissues may not suffer If, however, the block is sudden, some tissues with a high oxygen demand may be unable to get along with a grossly reduced supply while the necessary permanent dilatation is in progress Again, disease of the collateral vessels may prevent the establishment of an adequate relief circulation in a reasonable time, so that even tissues with less urgent oxygen requirements may die The term "functional end-artery" is therefore a poor one, since there is hardly an artery in the body that cannot be brought into this category by the force of circumstances Thus in arteriosclerosis the lumen of a diseased artery anywhere in the body may be suddenly occluded, and the collateral vessels may be in no condition to meet the demand Even the skin, the traditional home of free anastomosis, is not immune, and Edwards[15] has pointed out that in an arteriosclerotic lower limb the occlusion of an artery supplying the skin may lead to a patch of cutaneous gangrene

Edwards also notes that one muscle occasionally becomes gangrenous while the rest of the limb is comparatively little affected, and suggests that this is due to the lack of adequate communication between the vessels supplying adjacent muscles, some main muscular vessels, in fact, behave as end-arteries Brash[16] has worked on the gross blood-supply of the muscles of the upper limb, but as yet there appears to be no full statement for the lower limb Blomfield[17] has studied the vascular patterns within some of the muscles of the lower limb and finds great variation in the degree of intramuscular anastomosis in different muscles For example, gracilis is well endowed, but tibialis anterior is not He correlates this variation with clinical findings such as the tibialis anterior syndrome,[18] in which the extensor muscles atrophy following exercise Compared with the effort expended on other aspects of muscle physiology, the vascular supply of human and animal muscle has been neglected Le Gros Clark[19] and Blomfield[17] have reviewed their own and other work on experimental ischæmia in animals In rabbits the interruption of a main vessel of supply to certain muscles leads to necrosis of a well-defined region of the muscle despite the existence of intramuscular anastomotic channels It is not known whether this happens because the collateral circulation is anatomically inadequate or because striated muscle can survive only a short time without oxygen

We hope that further clinical work on the lines followed by Edwards will be supplemented by basic observations on experimental ischæmia and on the anatomy of the blood-supply to muscles

SMALL-QUANTITY BLOOD TESTS FOR SYPHILIS

HITHERTO we have had no authoritative evaluation of the various micro serological tests for syphilis Now however, the venereal diseases section of the United States Public Health Service has filled this gap[20–24]

Of the tests described, the micro-modification of the Venereal Disease Reference Laboratory (V.D R L) test requires 0 015 ml of serum, the filter-paper microscopic (F P M) test is done on a saline extract of a drop (0 05 ml) of whole blood dried on a strip of filter-paper, while the Chediak test requires 0 05 ml of whole blood dried on a glass slide These last two tests can be used as "detector" reactions in field operations Five laboratories participated in the comparative tests, and all reactions were measured on the fourth day after the donors were bled

The four modifications of the Chediak test (Chediak Kline, Chediak Mazzini, Chediak-Kahn, Chediak V D R L) proved more specific and sensitive than the original Chediak test itself, but the Chediak-Kahn and Chediak V D R L modifications were much less specific than the other two, and gave a much higher proportion of non syphilitic reactions The Chediak-V D R L modification has the advantage that results can be reproduced in different laboratories

This study seems to show that these micro tests are inferior both in sensitivity and specificity to the usual serum tests, and should be avoided if possible If venepuncture proves impracticable, enough blood for such a test can usually be obtained by the intelligent use of a guarded safety-razor blade Secondly it appears that the micro-V D R L test is superior to the other micro tests, but loss of specimens either in transit or in the laboratory (amounting to 8% in the American investigation) cannot be ignored Thirdly, all varieties of the Chediak test show a loss of sensitivity when carried out on specimens stored for more than 24 hours Fourthly, the F P M test is much less sensitive than the usual serum tests, and its use should therefore be limited to some field operations Finally, the value of micro tests for syphilis is greatest in mass testing of a population remote from a fully equipped laboratory The choice of these tests is influenced by the type of donor, geography, the interval between collection and testing, the capacity of the field laboratory to do the tests, and the fact that with relatively untrained personnel all specimens are likely to be collected successfully s treated by standard methods in the period of stigation.

THE INFECTING ORGANISM

he old doctrine that "if you take care of the gram-tives, the gram-negatives will take care of them-es" dies hard. It has already been shown (table I) penicillin-resistant organisms play some part, and opinion has been given that these occur mainly in ons which have been discharging before they come treatment. We have often observed also that, if of the factors mentioned above has operated and re is any delay in healing, a penicillin-sensitive anism is superseded by, or changes into, a penicillin-istant one. This is in line with findings by other kers on other types of wound (Summers 1952) and vadays is to be expected. Secondary infection in pital, even if staphylococcal, is very often penicillin-istant.

On all counts, therefore, the first day or two in the atment of paronychia are the crucial ones, and it is ential, to obtain consistently good results, that treat-nt shall be prompt, surgery shall be precise, and other cillary forms of therapy shall be overwhelmingly ective. This forbids one to wait for a bacteriological ort before defining treatment.

The data we have accumulated lead us to suppose it the infection is probably penicillin-sensitive, but y not be so; and that it is almost certain to be sitive to chloramphenicol.

ROUTINE

In this clinic I am not yet prepared to use chloram-enicol systemically for the routine treatment of septic nds, because a penicillin routine is still proving out-ndingly successful in over 95% of cases, because l exhibition is unreliable in outpatients, because of pense, and because of the possible side-effects of oramphenicol (*Lancet* 1952). Nevertheless the topi-use of chloramphenicol, reported as being highly cessful in other wounds (Flint et al. 1952), offers means of attacking those which might defy the nicillin.

Ellis (1951) reported his observations on high initial nicillin dosage, and he used it in the treatment of ronychia (Ellis 1952). He reports 90 to 95% four-y cures by incising alongside the nail fold, evacuating pus, and putting a dry dressing over the incision. does not remove any nail. In the localised unruptured es this appears eminently reasonable; but, since re is a considerable incidence in this area of cases th extensive subcuticular spread ("run-arounds" d "floaters") and of ruptured lesions already possibly ensitive to penicillin, I have been led to use topical loramphenicol, after removal of detached nail, in dition to penicillin in cases which are unlocalised or discharging.

In this way one hopes to anticipate a gram-negative ection while treating for a lesion still predominantly nicillin-sensitive.

The routine operative treatment now adopted may erefore be summarised as follows:

1) All cases have high preoperative penicillin dosage, rt of which, at least, is readily absorbed aqueous penicillin G, d further penicillin on the first postoperative day.

(2) Unruptured well-localised lesions have a small precise ision alongside the nail fold. The pus is evacuated, the jacent nail raised, and any pus dried out, but no il removed. A dry dressing is applied and inspected the second or third postoperative day (the "Ellis" eration).

(3) Ruptured paronychia, or those with much subcuticular ead, have Pilcher's operation and are dressed with a wick chloramphenicol (5%) in propylene glycol. Subsequent dressings of the same may be required on one or two occasions.

(4) All cases not obviously healthy and healing on the third or fourth day are treated by a toilet of the nail fold and with chloramphenicol drops two or three times weekly.

TABLE II—RESULTS OF TREATMENT OF PARONYCHIA

Operation	No. of cases	Incapacity (days)	Postoperative attendance (days)	No. of cases lasting more than 7 days	Longest healing-time (days)
Ellis (penicillin only) ..	20	5·0	4·75	2	11
Pilcher (penicillin and chlor-amphenicol)..	27	5·0	4·5	2	11
Resolution without operation	4	4·2	—	—	5
Others (Pilcher with penicillin only)..	7	8·7	8·7	4	13
Total	58	5·4*	5·1	—	—

* The average incapacity for all cases treated in the corresponding months in 1951 was 11·4 days and in 1950 12·8 days.

It has not been considered necessary to describe or to tabulate all the cases for this report. Note is taken of the type of lesion, and it is put into one of three classes. Bacteriological examination was made in many of the cases (table I). The results shown in table II include all cases coming up for treatment in an unbroken series (except 2 cases in which operation was refused), and no "mitigating circumstances" or "excuses" have been accepted. They include operations by one surgeon, two registrars, and five or six house-surgeons, according to chance. Seven operations done by others not briefed for the experimental period have been included but assessed separately from the foregoing.

CONCLUSION

The table of results is self-explanatory. We have adopted as a routine the principles defined in the later part of this paper. Although the periods of incapacity for the two methods seem to be the same, there is a place for both. Ellis's operation is followed by a more comfortable postoperative course and a quicker return to an uncovered finger, because no nail has been removed: it will be found applicable to a larger proportion of cases than the 30% reported. Nevertheless, a short series of cultures indicates that 15–20% of cases of paronychia may resist the use of penicillin; this incidence is higher than for other septic conditions of the hand. Ellis's operation on an insensitive infection will probably fail. The use of local applications of chloramphenicol, instead of penicillin lactose, with Pilcher's operation, seems to have prevented the occurrence of those refractory cases which previously kept the average high. As a result the recovery period for all cases has been reduced by half.

I have already recorded my constant debt to the nurses and to a succession of enthusiastic residents for their continued interest in the Hand Clinic. I must further pay grateful tribute to Dr. James Wilson and his department of pathology for their bacteriological work, and to record an acknowledgment of the work of Prof. Pilcher and Mr. David Bailey, and of Mr. Maurice Ellis at the General Infirmary at Leeds, whose progressive ideas are a constant stimulation.

Special Articles

THE FIREGUARDS ACT

LEONARD COLEBROOK
M B Lond, F R C O G, F R C S, F R S
LATE DIRECTOR OF THE MEDICAL RESEARCH COUNCIL BURNS UNIT, BIRMINGHAM ACCIDENT HOSPITAL

UNDER the Fireguards Act, 1952, it will become an offence for any person to sell or hire (except in certain specified circumstances) an electric or gas fire or oil-burning space-heater which is not fitted with a guard conforming to prescribed safety regulations The Act gives the Secretary of State power to issue these regulations, and to decide when the Act shall come into operation

In framing the regulations the Secretary of State will no doubt be largely influenced by the findings of the British Standards Institution committee, which were set out in the new standard no 1670 (1951) for electric fires, and amendment no 1 to British standard 1250/1946 for the most dangerous types of gas fire

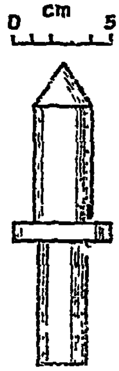

Fig 1—The testing cone. (With acknowledgments to the British Standards Institution)

In the standard for electric fires it was laid down that the safety or otherwise of any particular type should be judged by two considerations

1 *Non accessibility of Live Parts*—This was to be determined by three specific tests, as follows

(*a*) By a dummy finger (preferably connected up to an indicator lamp) of specified dimensions, which, when passed through any apertures *in the case* of the fire, does not reach any live parts

(*b*) By a testing cone (fig 1) which must not be able to pass through any aperture *in the dress guard* and touch the element or elements at any point

(*c*) By measurement of the distance between the element or elements and the guard In the case of reflector fires with spiral wire elements this distance must not be less than 1 in In the case of fires heated by a " fire bar " element (i e , a helix of resistance wire mounted on a fireclay support), the distance must not be less than 2 in at the centre of the element, and $1^{1}/_{2}$ in at the extremities

2 *Heat Intensity at the Face of the Dress guard*—This was to be roughly determined by the effect of the heat upon a readily flammable fabric such as flannelette If a piece of this material laid on the guard with the fire at full heat, does not " smoulder or ignite " within 10 seconds, the guarding is considered adequate (at least for the protection of able bodied adults)

The standard specifications speak at one point (clause 17) of " scorching " of the flannelette, and at another point (clause 25) of " smouldering " It should be noted that the time of exposure needed to produce these two effects is often widely different Moreover, although these specifications have been drawn up by the British Standards Institution, manufacturers are not required by law to conform to them Some manufacturers have announced their intention to do so, but there are already indications that others will not Qu recently (November, 1952) an inexpensive reflector fire (retail price under £2) has been put on the market with a neat wire-mesh guard which is fixed *at only* $^{1}/_{8}$ *in* from the fire-bar, so that it clearly fails to conform to the British standard specifications When this fire and guard was tested for heat intensity, it was found that white flannelette began to scorch at 7 seconds, and was blackened at 10 seconds, but did not begin to smoulder until 18 seconds The fire carried no maker's name The retailer who showed it to me assured me that it would sell much more readily than one with an adequate guard made by a firm of good reputation at a much higher price

The standard for gas fires applies only to " portable gas fires and gas fires fitted above hearth level having exposed flames or radiants " Its safety clauses are similar to those for electric fires, but the one dealing with non-accessibility of the heated element is judged by a cone test only, and in its dimensions differs somewhat from that employed for electric fires The heat intensity test is identical with that for electric fires, but here again the value of the test depends largely upon whether scorching or smouldering is taken as the danger point Since these fires tend to be somewhat hotter than electric fires the margin of safety secured by the B S I specifications for their dress guards is correspondingly less

NEW GUARDS FOR OLD FIRES

The passing of this Act was an important step in the elimination of burning accidents from our homes But it is not enough For the Act takes no account of the (estimated) 4–5 million gas and electric fires already in use in homes, offices, hospitals, and elsewhere in England and Wales—to say nothing of the coal fires, which are believed to number something like 12 million These various types of fires have been involved in, if not entirely responsible for, approximately 2400 severe burning accidents a year since the war—that is, nearly 7 a day About 280 of them each year have proved fatal, and 75% of these accidents have happened to children, to people over 65 years of age, or to epileptics If most of these fires continue in use for some years, as they well may, and continue to be (for the most part) unguarded, in homes where there are children, old people, or epileptics, we must expect that they will still contribute to as many tragic accidents as they have done in the past

It is for the public to deal with this unfortunate situation—the Government cannot do so Many people during the last few years have improvised guards for their electric fires—from cake-trays, wire letter baskets, and the like Others have exercised their ingenuity in devising guards specially suited to the several types of

e had upper abdominal pain for two days. In March, 1947, e was seen in a follow-up department, and a note was made at the pelvic mass was unchanged. At this time she was ll complaining of epigastric pain from time to time.

In June, 1948, the niece with whom she lived wrote to say at her attacks were now very frequent, that her face was a astly yellow, and that she looked very aged. She was seen the radiotherapy follow-up clinic and found to have nsiderable enlargement of the liver and spleen as well as ep jaundice. There was some doubt about the diagnosis of etastases, and she was referred to the medical unit for further vestigation. A straight radiograph showed no evidence of ll-stones, and a blood-count showed Hb 70%, 3,890,000 red lls per c.mm., and 6400 white cells per c.mm. (polymorphs)%). On July 16, 1948, she was admitted under the care of e medical unit with a provisional diagnosis of hepatitis. xamination showed a grey-haired woman with xanthoma elow the eyes. There was deep jaundice. The liver and leen were enlarged, and the gall-bladder was not palpable. er blood-pressure was 200/100 mm. Hg. and the urine ntained bile.

During the next four weeks she had four attacks of right bcostal pain with nausea and flatulence, but with no increase the jaundice. After this she improved; the jaundice ecreased, and the stools became coloured.

Ten months later, on May 2, 1949, she was again admitted fter several severe attacks of biliary colic. Her condition was uch the same as on the previous admission, except that she ow had severe pruritus and was feverish and sweating. On ay 7, 1949, she was transferred to the surgical unit and two rge gall-stones were removed, one from the common bile-uct, the other from the gall-bladder. There was pus in the all-bladder and in the bile-ducts. The liver was enlarged, and its surface was nodular; the tissue was friable and bled easily. The spleen was enlarged, and the portal-vein tributaries were greatly distended. There was no ascites. It was thought wise not to take a biopsy specimen. Recovery following operation was satisfactory, but shortly after discharge the patient had to be readmitted with pyrexia. This was considered to be due to cholangitis; it responded well to treatment with antibiotics.

Follow-up.—The patient is somewhat temperamental, and it was difficult to persuade her to attend the follow-up clinic again. In response to several requests she attended on Nov. 20, 1951, when she was of a good colour, very energetic, and eating well. She said that her bowels were a little looser since the operation. The xanthoma under the eyes was thought to be less pronounced. The accompanying table and figure show the completeness with which liver function has apparently returned to normal.

Reviews of Books

Ciba Foundation Colloquia on Endocrinology

Vol. 4. Anterior Pituitary Secretion and Hormonal Influences in Water Metabolism. Editor: G. E. W. WOLSTENHOLME, O.B.E., M.A., M.B., assisted by MARGARET P. CAMERON, M.A., A.B.L.S. London: J. & A. Churchill. 1952. Pp. 591. 45s.

THIS volume is the largest of the four Ciba Foundation Colloquia on Endocrinology so far published, and like the others it includes two separate symposia.

The larger and more recent of these was devoted to the anterior-pituitary gland and was noteworthy for the number of outstanding authorities who participated. They covered the anatomical, histological, and cytological aspects, including the cytochemical localisation of pituitary protein hormones, and the controversial question of the secretory innervation of the glandular cells of the hypophysis. One session dealt with the hypothalamic control of the secretory function of the hypophysis, many of the contributions being concerned with the mechanism of A.C.T.H. release. A paper on *p*-hydroxypropiophenone (which some believe specifically affects certain pituitary functions) heralds further studies of chemical control of pituitary function. The rest of the sessions dealt with the physiology and biochemistry of the six known anterior-lobe hormones. The whole is a fascinating record of recent research.

At the second conference, less ambitious in scope, the theme of hormones and water metabolism revealed the great advances in our knowledge of the relation of steroid hormones and hormones of both pituitary lobes to fluid and electrolyte metabolism. The adrenal cortex is a ubiquitous participant in a bewildering variety of metabolic functions.

This volume is impressive testimony to the excellent work of the Ciba Foundation in promoting an exchange of up-to-date information between workers in various countries. Moreover, it is a well-made book. The records of the discussion following each paper must have undergone some editing, for they are neither disjointed nor scrappy, but they nevertheless preserve the vivid atmosphere of informality aimed at by the organisers of the colloquia.

The old "nursery" type is usually too large for the modern small home, whose kitchen is also the living room The smaller fold-up types are usually devoid of any effective means of fixing them to the fireplace, so that a child can and often does remove them They have also to be removed for re-fuelling or stoking the fire It is to be hoped that it may soon become standard building practice (and enforced by local authorities) to provide staples at the side of the hearth to which guards can be securely hooked

Meanwhile a new design has been introduced which dispenses with the need for such staples and certainly seems worthy of a thorough trial It is the 'Braddell' guard (fig 4), sponsored by the Women's Advisory Council for Solid Fuel, which is now made (for the trade only) by Messrs Duke Waring, & Crisp Co, of London This guard is fixed to the chimney by two strong spring-loaded hooks It has also a large gate, fastened by a strong dog lead type of clip which a child cannot easily undo And it can be folded up and put away when not required

A rather more substantial and larger guard which is favoured by the Edinburgh Accident Prevention Council and the Scottish Department of Health is that shown in fig 5 It allows the fire to be re fuelled through the top, and it is adaptable to grates of different sizes by virtue of the telescopic construction of the front This latter feature also enables it to be folded into a comparatively small space when not in use Guards of this type are hired by the Edinburgh Accident Prevention Council, to householders who cannot afford to buy them, for the sum of 5s a year I am informed that there is a long waiting-list for them

Neither of these guards is spark-proof To make them so it would be necessary to use a guard of much smaller mesh, which would hide the fire Such guards would probably not be used It has therefore been thought better to concentrate on the greater danger—that of direct contact of clothing with the fire

The guards shown in figs 2(*a*) and 3(*c*) are made by Messrs J Broughton & Sons Ltd, of 234, Pershore Road South, King's Norton, Birmingham, 30, under the trade name of 'Lumley' guards Those shown in figs 2(*b*) and (*c*) are sold as 'Ann D' guards and are made by the Kleerun Co, Lane End, High Wycombe, Bucks The illustrations fig 2(*a*) and fig 3 are borrowed, by kind permission of the town clerk of Birmingham, from the leaflet *Advice on Fireguards*, issued by the city council

THE MEDICAL SERVICES IN THE KOREAN WAR

FROM A CORRESPONDENT

It is now over two years since the British 27th brigade, and later the 29th, joined the fighting in Korea The medical problems of any campaign are those of collection, first-aid evacuation, and definitive treatment of the sick and wounded, but particular circumstances determine what is practicable and the results that can be obtained The relatively static battle lines which have developed during so much of the Korean fighting have been compared to the western front of the 1914–18 war, and the description "Passchendaele of the hilltops" has been used Another comparison was made by a former D D M S of the 5th Corps in Tunisia, who, during a visit to Korea, said that if he had been led blindfold into the forward areas in the British zone it would have been difficult for him to tell that he was not back in Tunisia, at any rate as far as the superficial appearances of terrain and of medical arrangements were concerned The medical services of the British Commonwealth Division have been working for over a year in this setting There are 3 field ambulances—Canadian, British and Indian The Indian field ambulance has attached to it a field surgical team There is a Canadian field dressing station and a Canadian field surgical team These forward units serve one of the new mobile army surgical hospitals (M A S H), in this case a Norwegian unit, and a Swedish Red Cross hospital

LINES OF EVACUATION

From Korea the wounded go to a combined hospital at Kure, in Japan, the British Commonwealth General Hospital, which is staffed by British, Australian and Canadian personnel, and where there is also a convalescent depot Although the British field ambulance deals mainly with the Norwegian M A S H, a proportion of casualties, including nearly all neurological cases are sent direct to American M A S H s which have well equipped neurosurgical teams The consultant supervision of all forward units and all hospitals in Japan is the responsibility of the consultants division of the medical section G H Q, United Nations and Far East Command Certain medical casualties are treated in Korea but all the others are evacuated by air to Japan and then by rail to the Commonwealth hospital Most of the neurosurgical cases pass from the M A S H along the American lines of evacuation to Japan, and are transferred later to the Commonwealth hospital From Japan the seriously wounded come home by air as soon as they are fit enough to travel The flight to Britain takes five or six days A certain number of casualties return by sea

In the early stages of the fighting, when things were going badly for United Nations troops, H M Hospital Ship *Maine* did very valuable work in transporting American and British casualties from Korea to Japan

MOBILE ARMY SURGICAL HOSPITALS

The M A S H has lately been introduced by the Americans It differs from our own casualty clearing station (C C S) in being limited to 100 beds and to surgical cases It is more mobile than the C C S, but it may prove of less general value than the C C S, especially in tropical countries where acute medical conditions are often a big medical responsibility The static lines in Korea are not a thorough test of its value, although the widespread use of antibiotics seems to have reduced the number of medical cases needing admission to hospital

HELICOPTERS

A special feature of the Korean campaign has been the use of helicopters in the evacuation of wounded These aircraft, flying between regimental aid-post and M A S H, have made it possible to give full surgical treatment to serious casualties within one to three hours of the man being wounded It has therefore been necessary to stop giving fluids by mouth in the regimental aid post to those injured who will be taken quickly to the surgeon in this way In one period of ten months 254 serious casualties were evacuated from the British zone by helicopter, 154 of these were wounded, and 100 represented other emergencies, including medical conditions

TYPES OF WOUND

The type of wound sustained in battle clearly depends a great deal on the weapon causing it One analysis of wounds in the Korean campaign was as follows

Mortar wounds	37%
Bomb and grenade wounds	21%
Gunshot wounds	17%
Shell and high explosive wounds	12%
Mines	6%
Battle accidents	6%
Burns	1%

This distribution is not unlike that seen during certain periods of the late war in Europe The risk of burns in battle has increased steadily over the last fifty years, and the low proportion of burns in this list is unusual Accidental napalm burns have shown no clinical differences from burns of equal severity due to other agents

THE LANCET

LONDON: SATURDAY, JAN. 17, 1953

Measles Encephalitis

THE biennial epidemic of measles is in full swing; England and Wales weekly notifications have ached the 30,000 mark. Encephalitis seems to especially liable to complicate measles during pidemics of the disease [1, 2]; its incidence during pidemics has been approximately estimated at 1 per 000 cases admitted to hospital.[1, 3–8] There seems o be no correlation between the severity of the attack f measles and the liability to encephalitis; so a ubstantially similar incidence of encephalitis is to e expected among cases treated at home. Yet erified cases of post-measles encephalitis notified n the years 1950 and 1951 numbered only 73 out of total of 983,900 notifications of cases of measles. t seems likely, therefore, that the reporting of acute ncephalitis under the 1949 Regulations has not yet got into its stride, and that many cases, possibly nild, are not being notified.

Measles encephalitis belongs clinically and pathoogically to the group of post-infectious encephalitis. This group also includes the encephalitis that may follow vaccinia, smallpox, chickenpox, rubella, occasionally mumps, and other virus infections. It usually appears suddenly and unexpectedly when the rash has just subsided leaving staining of the skin—that is, about the 3rd post-eruptive day. It may start, however, at any time between the 4th and the 14th days of the disease or, very rarely, in the pre-eruptive stage.[9] In one series of 74 cases the age-distribution ranged from 14 months to 35 years [7]; but about half the cases are in children aged 5–8 years.[6] The fatality-rate varies from 10 to 30%. The earliest histological lesion, according to APPELBAUM and his colleagues,[7] is cellular infiltration of the adventitia of small and medium veins in the grey and white matter of the brain. In cases where neurological symptoms have been present more than 3 days before death there are, in addition, perivascular demyelination, infiltration of the demyelinated areas with microglial cells, and small areas of softening in the white matter. Usually there is also significant cellular degeneration, and many ganglion cells may be missing. Such changes have been interpreted as inflammatory; and in one case virus was recovered from the brain of a child who died of post-measles encephalitis 9 days after the rash appeared.[10] The alternative interpretation of these changes is that they are an allergic response to the virus of measles; and for this view there is much weighty evidence.

The clinical course is very variable and may include cortical, brain-stem, myelitic, and meningeal signs. Fortunately, in the great majority rapid recovery sets in after 2–3 days of pyrexia, coma, convulsions, or other central nervous disturbance. When coma and other symptoms continue longer, neurological recovery is usually slower; but recovery is progressive and, with some exceptions, virtually complete after weeks, months, or years according to the extent of the damage. The potential reversibility of all the lesions has been emphasised by JENNINGS,[11] who showed in particular that blindness almost always clears up although it may take some years to do so. The electro-encephalogram (E.E.G.) during the acute stage shows gross high-voltage slowing in all leads; judged by the E.E.G., recovery is slower than the apparent clinical recovery, and it is not always complete even after 4 or 5 years.[12]

The ultimate prognosis has now been further examined in a psychological follow-up study by MEYER and BYERS [13] of 16 cases treated in the Children's Hospital, Boston, between 1943 and 1949. This reveals that abnormalities of mental function can be demonstrated by appropriate psychological tests in a high proportion after neurological and E.E.G. evidences of the disease have cleared. Easy fatigability of intellectual function and defects in attention, in perceptual-spatial organisation, and in learning capacity tend to persist for months, or even permanently, in about a third of the children—usually those who have had a long acute stage. When such psychological defects persist, the child has difficulty in acquiring new knowledge, and consequently his intelligence quotient falls gradually over the years. His defective powers of adaptation tend also to produce emotional stress and either a retreat into himself or aggressive rebellion. Such children need to be handled tactfully, affectionately, patiently, and with due allowance for their mental disabilities; they must not be pressed either in school or in the home. The outcome is influenced by age at the time of the attack. Older children, because of their more elaborate foundation, are more likely to remain competitive despite incomplete intellectual recovery than are younger children who must acquire their fundamental learning with defective tools. MEYER and BYERS have stated a good case for detailed psychological assessment of cases of encephalitis where the patient, after apparent recovery, shows behaviour difficulties, personality change, or some loss of intellectual capacity. Thereby a way of life may be planned which will diminish anxiety and tension and improve behaviour.

THE MEDICAL SERVICES IN THE KOREAN WAR

FROM A CORRESPONDENT

It is now over two years since the British 27th brigade, and later the 29th, joined the fighting in Korea The medical problems of any campaign are those of collection, first-aid, evacuation, and definitive treatment of the sick and wounded, but particular circumstances determine what is practicable and the results that can be obtained The relatively static battle lines which have developed during so much of the Korean fighting have been compared to the western front of the 1914–18 war, and the description "Passchendaele of the hilltops" has been used Another comparison was made by a former D D M S of the 5th Corps in Tunisia, who, during a visit to Korea, said that if he had been led blindfold into the forward areas in the British zone it would have been difficult for him to tell that he was not back in Tunisia, at any rate as far as the superficial appearances of terrain and of medical arrangements were concerned The medical services of the British Commonwealth Division have been working for over a year in this setting There are 3 field ambulances—Canadian, British, and Indian The Indian field ambulance has attached to it a field surgical team There is a Canadian field dressing station and a Canadian field surgical team These forward units serve one of the new mobile army surgical hospitals (M A S H), in this case a Norwegian unit, and a Swedish Red Cross hospital

LINES OF EVACUATION

From Korea the wounded go to a combined hospital at Kure, in Japan, the British Commonwealth General Hospital, which is staffed by British, Australian, and Canadian personnel, and where there is also a convalescent depot Although the British field ambulance deals mainly with the Norwegian M A S H, a proportion of casualties, including nearly all neurological cases, are sent direct to American M A S H S which have well equipped neurosurgical teams The consultant supervision of the forward units and all hospitals in Japan is the responsibility of the consultants division of the medical section G H Q, United Nations and Far East Command Certain medical casualties are treated in Korea but all the others are evacuated by air to Japan and then by rail to the Commonwealth hospital Most of the neurosurgical cases pass from the M A S H along the American lines of evacuation to Japan, and are transferred later to the Commonwealth hospital From Japan the seriously wounded come home by air as soon as they are fit enough to travel The flight to Britain takes five or six days A certain number of casualties return by sea

In the early stages of the fighting, when things were going badly for United Nations troops, H M Hospital Ship *Maine* did very valuable work in transporting American and British casualties from Korea to Japan

MOBILE ARMY SURGICAL HOSPITALS

The M A S H has lately been introduced by the Americans It differs from our own casualty clearing station (C C S) in being limited to 100 beds and to surgical cases It is more mobile than the C C S, but it may prove of less general value than the C C S, especially in tropical countries where acute medical conditions are often a big medical responsibility The static lines in Korea are not a thorough test of its value, although the widespread use of antibiotics seems to have reduced the number of medical cases needing admission to hospital

HELICOPTERS

A special feature of the Korean campaign has been the use of helicopters in the evacuation of wounded These aircraft, flying between regimental aid-post and M.A.S.H., have made it possible to give full surgical treatment to serious casualties within one to three hours of the man being wounded It has therefore been necessary to stop giving fluids by mouth in the regimental aid post to those injured who will be taken quickly to the surgeon in this way In one period of ten months 254 serious casualties were evacuated from the British zone by helicopter, 154 of these were wounded, and 100 represented other emergencies, including medical condition

TYPES OF WOUND

The type of wound sustained in battle clearly depends a great deal on the weapon causing it One analysis of wounds in the Korean campaign was as follows

Mortar wounds	37%
Bomb and grenade wounds	21%
Gunshot wounds	17%
Shell and high explosive wounds	12%
Mines	6%
Battle accidents	6%
Burns	1%

This distribution is not unlike that seen during certain periods of the late war in Europe The risk of burns in battle has increased steadily over the last fifty years and the low proportion of burns in this list is unusual Accidental napalm burns have shown no clinical differences from burns of equal severity due to other agent ef in 64% of cases; but WALDRIFF and his col-gues rightly emphasise the inadvisability of treating this method acute or subacute vesicular dermatitis widespread dermatitis. MADDEN[11] treated 141 cases various selected dermatoses with 'Thephorin' henindamine hydrogen tartrate) ointment and ported relief in 90%, no change in 5%, and worsening 5%.

ELLIS and BUNDICK[12] received 200 replies to a estionary which they sent to 265 dermatologists in e United States and Canada. 94% of these derma-logists reported that they had used anti-histamine ugs in the past, but only 10% continued to use em often; 50% were using them occasionally, while e remaining 40% were not using them at all. easons for discontinuing their use were the belief at they were ineffective, or liable to sensitise the in, or to aggravate dermatosis. Sensitisation actions were commonest with thephorin, followed tripelennamine ('Pyribenzamine') and diphen-ydramine ('Benadryl'); but thephorin relieved ching the most effectively. It was generally felt hat these substances were useful for anogenital ruritus and neurodermatitis, but that they were of ttle help in moist areas. About a quarter of the ermatologists thought that the local use of anti-istamines was of value; about a third were oubtful; and the remainder (approximately two-ifths) thought they were useless: 29% suggested hat anti-histamines for local use should be taken off he market. The only report of controlled trials has een by BALDRIDGE,[13] who treated 41 patients with % thephorin ointment on one side and with its nmedicated base on the other. These were presented o the patient as "slightly different forms of the same nedication," and the patients were asked to estimate he percentage of relief on the two sides. The areas reated with thephorin were reported on the average s 47% relieved, and the areas treated with the nmedicated base as 49% relieved. These results re a chastening reminder of the powerful influence f suggestion in treatment, particularly when symptoms of emotionally influenced disorders are being ountered, and when remedies are "put across" with enthusiastic expectancy (as they should be in umanistic medicine).

Anti-histamine drugs vary in their skin-sensitising power; but usually 2–6% of cases become sensitised. It is therefore especially important to know whether these are really effective antipruritic agents. It is surely significant that the local use of these drugs is confined almost entirely to the neurodermatoses; for there is increasing evidence that in these conditions the pruritus is produced in the first place by emotional disturbance, though no doubt it is often aggravated by friction and local applications. It seems irrational to expect local applications to relieve a symptom which has been brought about by frustration of emotional expression. The lessening of emotional tension by the abatement or removal of a conflict situation, or by the adoption of a more nearly physiological mode of emotional expression, is the essence of relief in these maladies; and any material treatment given about the same time may undeservedly be credited with the "cure." The dermatologist is familiar, too, with the obstinate and irrepressible neurodermatoses which if relieved at one site erupt at another, indicating the seething unrest beneath; and he is also aware that the scratched and rubbed nucha or wrist may sometimes represent a genteel way of relieving an itchy anus. The value of topical anti-histamines would seem to be "not proven"; and the doctor who thinks of using them should pay due regard to their sensitising power, which is midway between that of the hazardous benzocaine derivatives and the old-fashioned but trustworthy oily calamine lotion.

Annotations

SOCIAL NEEDS: A RETROSPECT

IT is not in man's nature to be unmoved by the acts of his fellows: we are changed, for good or evil, by what goes on around us. In this country, the events of our history and the temper of our people have combined to make us build a State in which the rights and welfare of the individual citizen are particularly honoured; and we are naturally happy that others should profit by our experience, both of failure and success. At the Anglo-German conference arranged by G.E.R.,[1] which has been held in London in the past week or so, speakers surveyed our social insurance, health, and welfare services, in the hope that the German experts who attended might find in them the answer to some of their own problems.

The present scene was set against the stormy background of our history by Prof. Richard Titmuss. Ours, he said, was once a peasant society, as Germany's was; and when a family fell on evil days its needs were met by the Church, by charity, and by the collective efforts of the parish towards the relief of the poor. In a rough sort of way this served very well. This pattern of charitable welfare and collective aid broke down when the amount of social need was violently changed by the first of the Industrial Revolutions, based on the steam-engine. It called into being a great society of wage-earners solely dependent on their labour power; and dependence on this power made them more dependent on the state of their health. Ours became—and still is—a society with no useful place for the sick, the disabled, the substandard, and the old: they have lost their labour power.

> "Simultaneously, this new industrial system based on the wage-earning capacity of the *individual* itself created new hazards to health and new problems in the rearing of children. As a result of the growth of town and city, factory and mine, new dangers to health and sanity appeared; new forms of mass disease arose; new social evils—psychological as well as physical—were generated. The stability of the family unit was threatened when the father left his home for six days out of seven to exchange his labour power for money; it was threatened too by a system of reward which ignored altogether his rôle as a father and his responsibilities for those who were too young or too old for industrial wage-earning work."

The Industrial Revolution, in fact, created social insecurity over the whole span of life, insecurity which the family could not remove by their own unaided efforts. By breaking up the family unit, selecting only those that industry could use and rejecting the rest, it created new problems of poverty and misery with which charity and the poor-law were unable to cope. In the 1840s Rudolf Virchow, the pathologist, led a strong public-health movement in Germany, claiming (almost

[1] A society for promoting Anglo-German educational relations, founded in 1942 to help German refugee teachers and social workers to prepare for post-war educational reconstruction in Germany, and now giving a reciprocal character to its work.

a few minutes each, the methods best suited to their particular subject Dr J Vallance-Owen taught on physical signs in the chest; Dr I McIntyre illustrated a convenient method of determining the alkali reserve, Dr G A K Missen questioned his class on a specimen of bacterial endocarditis from the pathology museum, Mr H H Bentall discussed a swelling in the breast at his ten-minute outpatients, and Dr E S Clarke guided his students through the examination of a man with a neurofibroma pressing on the cervical cord.

Some of the audience found it hard to see and follow all the details, but this was no serious criticism, for the methods used were designed for a more intimate atmosphere than that of the lecture theatre

Discussing the technique of outpatient teaching, Dr R C Mac Keith suggested that a session set aside largely for teaching, with only four patients instead of the usual dozen or more, would help the teachers, who often found it difficult to give students the time they needed to reach their diagnosis On the other hand, Professor Aird thought that the steady stream of patients brought the pages of the textbook to life in a very profitable way Professor McMichael added that a particular value of outpatient teaching was the opportunity it gave for students to see patients who had recovered, often from diseases with a serious prognosis

HEALTH UNDER INDIA'S FIVE-YEAR PLAN

Under India's first Five-Year Plan, approved by both houses of parliament, the health programme embraces the following priorities (1) provision of water-supply and sanitation, (2) control of malaria, (3) preventive health care of the rural population through health and mobile units, (4) health services for mothers and children, (5) education and training and health education, (6) self-sufficiency in drugs and equipment, and (7) family planning and population control The medical and public-health plans of the central and State governments will cost Rs 995 5 million The central government will aid the States in higher education and research and in certain specific schemes

Of the total outlay on medical programmes, more than 50% will be on hospitals and dispensaries, and nearly 40% on medical education and training, in addition to the establishment of the All-India Medical Institute, the completion of new medical colleges in Assam, Bombay, Madras, Madhya Pradesh, West Bengal, and Travancore-Cochin, upgrading of existing medical schools, and provision of training for auxiliary medical personnel including nurses, midwives, and compounders

The execution of these schemes is expected to increase the total number of personnel trained thus

	NUMBER TRAINED DURING YEAR ENDING 1950–51	1955–56	Increase %
Doctors	2504	2782	11 1
Compounders	894	1621	81 3
Nurses	2212	3000	35 6
Vaids and hakims	914	1117	22 2

The increase in the number of hospitals and dispensaries and the number of beds in them is expected to be as follows

	During 1950–51	By 1955–56	Increase %
No of hospitals	201	206	2 4
No of dispensaries			
Urban	1358	1695	24 8
Rural	5229	5840	11 6
No of beds in hospitals	106 478	117,222	10 1
No of beds in dispensaries			
Urban	2013	2233	11 4
Rural	5066	5582	18 2

The expenditure on public-health programmes undertaken by the central and State governments is Rs 503 8 million. Water-supply, drainage, and anti-malaria schemes account for the bulk of the expenditure

Malaria is the most important public-health problem in India and its control is naturally accorded the highest priority Over Rs 170 million has been provided in t plan for malaria control The operational programme the malaria plan is based on the use of insectic residual spraying in rural areas, protecting 200 mill people, and treatment with anti-malaria drugs Th plan also embraces the construction of two D D T pl to ensure sufficient supply of D D T at reduced cos This project is financed jointly by the central and t State governments

Tuberculosis ranks next in importance to malaria a a health problem to India In this case the schem generally relate to sanatoria, hospitals, and clinics, BCG vaccination teams Compared with 1950-51 t plan envisages the following increase by 1955-56

	1950–51 No of institutions	No of beds	1955–56 No of institutions	No o be
Sanatoria	37	4161	46	[illegible]
Hospitals	48	3077	50	[illegible]
Clinics	127	2323	180	[illegible]

Specific recommendations have also been made for t control of venereal diseases, for maternity and ch welfare, for medical education, and for research

The recent steep increase in the population of th country has brought to the fore the urgency of fami planning and population control Family limitation deemed both desirable and necessary for safeguard the health of the mother and for the better care an upbringing of the children The Five-Year Plan provid Rs 6 5 million for family-planning measures It al suggests the constitution of policy and research com mittees, and a population commission at a later date

NEW YEAR HONOURS

The list appearing in our last issue omitted the nam of two members of our profession on whom honours hav been conferred They are

Knight Bachelor

Frank Percivale Montgomery, M C, M B Belf, F F
Consulting radiologist, Down County Infirmary a
Ulster Hospital for Children and Women

C B E (Civil)

Louis Boyd Neel, M R C S
Musical director, founder of the Boyd Neel Orchestra

In the community of Northern Ireland Dr Montgomery holds a leading position won by distinction in several different fields, including that of International rugby, and his public work has latterly included the chair manship *of the Northern Ireland Hospitals Authority*

Medicine and the Law

Fatal Poisoning by Mothballs

A boy, aged 21 months, died the day after he had eaten a number of mothballs which he found in a wardrobe in his home At the inquest at Bromley, Kent, on Jan 8 [1] the pathologist reported that the child died of a respiratory failure which was in keeping with naphthalene poisoning He added that the literature on the subject tended to suggest that the majority of such cases were not fatal Asked whether there was no antidote to mothball poisoning, he replied "As far as we know there is none" The coroner inquired "Assuming the stomach had been washed out early enough and thoroughly enough, could the child still have absorbed the poison?" "Yes The poison could have got into the intestines and affected the liver"

Recording a verdict of death by misadventure, the coroner warned parents to regard mothballs as a dangerous poison which should be kept out of reach of children which gives rise to true "colic." Morphine, which ically brings about constipation as well as relief of ı, seems to increase tone with obliteration of the gut en while greatly reducing propulsive type-3 waves.

---

[1] *Manchester Guardian*, Jan 9, 1952

[ovements of the colon differ from those of the small stine in many ways: type-1 ("mixing") waves are frequent in the lower bowel, while type-2 waves, h lasting about 30 seconds, are of greater pressure; s these waves that account for the haustration seen iographically. The so-called mass movement of the n—a very infrequent propulsive wave—is confined the large intestine. In normal people colon motility xtremely variable; periods of activity alternate with iods of inactivity, and both are greatly influenced by emotional state. In patients with chronic ulcerative itis the total colonic activity seems to be reduced, with eneral change from the mixing to the propulsive type movement. In the colon, as in the small intestine, rphine tends to increase the non-propulsive move-nts and to decrease the propulsive.

Ve still do not know the exact relation of absorption food to the frequency and strength of the different estinal movements, nor of the varying rates of absorp-n of different substances to the amount of mixing they dergo in the small intestine. These and allied problems er a fruitful field for further investigations.

STILLBIRTHS AND NEONATAL DEATHS

Two factors in particular seem to have largely counted for the decline in the number of stillbirths d neonatal deaths. These factors are better social nditions and a higher standard of obstetric practice. first both seemed equally important; but with e continued decline in the stillbirth and neonatal death tes their influence became less distinct and their relative portance changed. With the establishment of adequate aternity services and a high general standard of living stetric causes were seen to account for a higher rcentage of deaths.

Workers[1] at Bristol, where the stillbirth and infant ath rates are low and the general standard of living is gh, have compared two series of stillbirths and neonatal aths with two groups of controls. No significant fference was found between cases and controls in cial factors, nor in the *amount* of antenatal care; portant differences were discovered, however, in the *ality* of obstetric care. For instance, many patients ith infants who were born dead or who died neo-tally were not seen by a consultant at any time ring the pregnancy or labour, although the number abnormalities among such patients was far greater an among controls. Commonly the reason for this as that labour began before the 34th–36th week, hen specialist appointments are normally made. It peared that there was a failure to appreciate that me cases may require specialist supervision at a much rlier stage in pregnancy than that normally regarded s routine. 44% of the stillbirths and 60% of the neonatal eaths were of infants with a birth weight below $5^1/_2$ lb. he most common complication of pregnancy was found be toxæmia. This condition, besides occupying first lace as a cause of maternal death, is the most common ondition known to be associated with prematurity.[2] ossibly the early signs of this condition were evident efore the 34th week; and had these signs been recog-ised, and specialist advice sought, some of these remature births might have been prevented.

It would appear that throughout the country antenatal are is often energetically practised along strictly outine lines. Thus patients are commonly weighed t each visit, yet any attempt to control weight-gain by diet is rare. Similarly, iron in tablets is given in large amounts to almost all patients; not always, however, is an attempt made to ensure that such tablets are taken, and that if they are taken the iron is absorbed and the patient's blood picture improves. The mounting list of routine investigations carried out on all patients at every visit to the clinic tends to divert attention more and more from the individual patient and from the true purpose of antenatal care—namely, the early detection of important abnormalities. The Bristol workers have given a timely reminder that much of the standard practice in antenatal care is due for reconsideration. Greater obstetric skill can prevent only a proportion of stillbirths[3]; but this proportion is by no means small.

INTRA-ŒSOPHAGEAL PRESSURE

By means of a modern electromanometer and some fine plastic tubing slipped through the nose, it is easy to record respiratory and cardiac fluctuations in the œsophagus. Recent work on both sides of the Atlantic has been concerned with two different aspects of such records—namely, as guides to general intrathoracic pressure and to certain cardiac events.

Dornhorst and Leathart[4] found good dynamic agreement between the pressures in the œsophagus and in a shallow pneumothorax and concluded that the intra-œsophageal pressure reflected intrathoracic pressure. Such measurements have been helpful in analysing circulatory events—for example, in Valsalva's manœuvre[5] and with pulsus paradoxus[6]—and, combined with a respiratory record, they provide a simple way of investigating the mechanical properties of the lungs and air-passages. The principles of this potentially valuable type of investigation were clearly set out twenty-five years ago by von Neergaard and Wirz,[7] but they have been little exploited because the original method necessitated puncturing the pleura—a possibly risky procedure in patients with pulmonary disease. An American team[8] has now confirmed the agreement between œsophageal and pleural pressures, and has used the method to construct volume-tension characteristics for normal and emphysematous lungs.[9] The further application of this technique—for example, to provide an objective measure of fibrosis in patients with silicosis—should yield information of interest and possibly of diagnostic or prognostic value.

The œsophageal-pressure record, especially when a water-filled system is used, shows cardiac pulsations which vary at different levels of the œsophagus and are often considerably larger than those in an intrapleural record. They must therefore depend on some local action of the heart-beat. It is natural to inquire what information they will yield about events in the heart, and especially in the left auricle which is in direct contact with the œsophagus. This question has been studied by Zoob[10] in this country and by Lasser et al.[11 12] in the U.S.A. A prime object has been to assist in the recognition of mitral incompetence—a diagnosis whose importance has been greatly enhanced by the introduction of valvotomy. Lasser and Loewe[11] showed that in dogs the œsophageal pulse agreed in form remarkably well with the pressure-pulse recorded directly from the left auricle, both before and after the production of mitral incompetence. In patients they have obtained

one of them regularly brought her daughter Of these, Miss H and both the domestic helps developed Q fever in September The family doctor (Dr W) and district nurse (Nurse N) attended old Mrs F before she died, and another doctor (Dr V) and 2 undertakers (Mr B and Mr Z) visited the farm after her death , but these 5 paid only short visits, and none of them developed Q fever

After excluding Mrs F , sen , there were in all 25 people at risk Of these, 5 adults had no clinical or serological evidence of infection, but 4 of them had paid only short visits to the farm One child remained well, but the presence of Q-fever antibodies six months after the outbreak suggested a subclinical infection An adult and 2 children also remained well, but no serological tests were performed All the other 16 adults developed clinical Q fever , this included everyone over the age of twelve who was living on the farm at the time of exposure

CLINICAL PICTURE

Although the attack-rate in this outbreak was unusually high and subclinical infections were rare, the clinical picture was very like that described in previous outbreaks and groups of sporadic infections Sudden onset with severe headache and fever was common to all, but clinical signs of pulmonary involvement were found in only 5 patients (In most cases X-ray examination was carried out too late to be of value) There were the usual wide variations in severity , 9 patients had mild febrile illnesses lasting less than a week, while 7 had more severe attacks lasting between one and seven weeks Symptomatic treatment only was given to most patients, and no noticeable benefit followed the use of a sulphonamide, penicillin, or streptomycin 6 patients were given chloramphenicol in various doses, starting between two and eight days after the onset, and they responded well The 2 oldest patients had the longest illnesses, lasting seven weeks and three weeks respectively, as the following case-histories show

Mrs P , the farmer s mother in law, aged fifty six, was taken ill in Berlin on Sept 7 with severe headache, fever, sweating, and insomnia Her condition improved slightly during the next day, but she became suddenly worse and was admitted to hospital on Sept 12 with dyspnœa, cyanosis, and signs of pneumonia of the left lower lobe Sulphonamides and penicillin produced no response, but on Sept 15 news of the other illnesses at the farm (not then diagnosed) reached her doctor, who immediately suspected Q fever and gave chloramphenicol The patient's temperature promptly fell to normal, but rose again when supplies of chloramphenicol ran out on Sept 24 There were now no radiological signs of pneumonia, but the patient was still very ill, and fever continued until fresh supplies of chloramphenicol became available and were given on Oct 13 The temperature again fell and her condition improved, but there was a further relapse as soon as the drug was stopped on Oct 20 However, after a third course, ending on Nov 2, the patient remained well and was discharged from hospital on Nov 19 The diagnosis of Q fever was confirmed by a rising titre of Q fever antibodies

TABLE III—PIGS ON FARM, WITH DATES OF PARTURITION A RESULTS OF LABORATORY TESTS

Name	Litter born	Serum tested	Result *
Snotch	Aug 10, 1951	Jan 28, 1952	Negative
Blowey	Aug 10, 1951	Jan 28 1952	Negative
Lady pig	Sept 4, 1951	Not tested	—
Flirt	Aug 18, 1951	April 10 1952	Non specific reac
Squib	Not pregnant	Not tested	—
Piglets			
Snotch 1–4	—	Jan 28, 1952	Negative
Snotch 5	—	April 10, 1952	Non specific reac
Blowey 1–4	—	Jan 28, 1952	Negative

* Pig sera were tes[illegible]
the conglutina-
tion test, and
reactions were
in the anti globulin sensitisation test

Mrs D , aged fifty six, one of the domestic helps, felt ill o *Sept 8, but, in spite of a feverish headache with pains in t* neck and limbs, she tried to continue her work On Sept 1 she took to bed, and was found to have signs of a bilater basal pneumonia A diagnosis of virus pneumonia was mad and she was given 0 25 g of chloramphenicol four hourly t to a total of 6 0 g In spite of the low dosage, her temperature fell to normal in thirty six hours, and the signs in her che rapidly cleared, but she remained very debilitated indeed a was confined to bed for three weeks

With the exception of Mrs X , one of the visitors *from London, whose illness was diagnosed on* clinical grounds alone, all the patients had Q fever antibodies in their serum when it was tested later Mrs P 's serum showed a rise in antibody titre from 1 in 128 to 1 in 51 and in the others the titres varied between 1 in 40 and 1 in 320 in specimens taken about one month after the illness The blood of 2 patients was not examined until later, and both showed Q-fever antibody titres of 1 in 20 while serum from Jill T , who was not ill at all, also had a titre of 1 in 20 when tested six months after the outbreak

SOURCE AND MODE OF INFECTION

The explosive nature of the outbreak suggested the exposure of completely susceptible individuals to a single large dose or to an unusually infective strain of *Rickettsia burneti* The peak of the outbreak was reached on Sept 6–8, and the mean day of onset was Sept so that, with the usual incubation period of about nineteen days, infection would have taken place about Aug 19 *This gives a minimum incubation period of* thirteen days for Maureen T , and a maximum of twenty nine days for Mrs C Fortunately 4 of the patients had visited the farm for short periods only during August, which suggested that infection must have occurred between Aug 16 and 19 (see table I and figure) Only 7 of the patients had been to the cottages, whereas all had visited the farmhouse or outbuildings during this period, except for Mrs J , the cowman's wife, who could not remember visiting the farmhouse after Aug 6 However, infection could well have been carried to Mrs J 's cottage by her husband's clothes or in the milk

ACERIN

THE discovery of a new bacteriostatic agent is unlikely arouse more than polite interest today, but a substance ctive against viruses is always news. Fischer[1] has studied e action of an extract from the fruit of the Norwegian aple (*Acer platanoides*) on a bacteriophage and on accinia virus. The active substance in these extracts, which he has given the provisional name "acerin," ppears to have a rapid phagicidal action on a *Bacterium li* bacteriophage in concentrations which do not inhibit he growth of the host bacterium. A small number of xperiments suggest that acerin may also have a virucidal ction on vaccinia virus. Apparently it has no significant ffect on a staphylococcus bacteriophage, and a few xperiments suggest that it is not toxic to mice and abbits in the dosages tested.

This is only a preliminary communication, and clearly uch more information is needed about the range of ctivity, mechanism of action, and chemical structure f acerin before deciding whether it will prove an important chemotherapeutic substance, giving the lead to more f its kind, or merely a laboratory curiosity.

OBJECTIVE TESTS FOR CORONARY INSUFFICIENCY

IN the absence of abnormal signs in the heart and lectrocardiogram, the diagnosis of coronary disease ften depends solely upon clinical interpretation of the istory. The story of angina pectoris is usually characeristic enough, but there are always a few patients with typical chest pain in whom objective evidence of oronary insufficiency would be valuable. Standard ests, based on the well-known capacity of exercise and noxæmia to provoke electrocardiographic changes imilar to those sometimes recorded in an anginal attack, ave been used for some time and found helpful. The xercise test consists in climbing steps either a fixed umber of times[2] or until pain or breathlessness appear.[3] n the anoxæmia test a mixture of 10% oxygen and 90% itrogen is breathed from an anæsthetic apparatus for eriods up to 20 minutes. The electrocardiogram may e affected in several ways: the chief changes are epression of the RST segment, inversion of the T wave, nd, more rarely, shortening of the P–R interval.[4] These hanges are found to a limited extent in apparently ealthy people in response to exercise or anoxæmia, but hen the RST depression in leads I, II, III, and IV totals mm. or more, or when there is inversion of the T wave ccompanied by RST depression of 1 mm. or more in ad I, they are generally regarded as abnormal.[5] [6] urner and Morton[7] have lately confirmed this view and mphasised the importance of using lead IV.

An abnormal response either to exercise or to anoxæmia ay be expected in between a quarter and a half of those ith known angina or with a history of infarction. The echanism of the changes is obscure, for their unpreictable appearance cannot be correlated with the egree of oxygen desaturation of the blood or with the tent of coronary arteriosclerosis.[8] However, provided at the effects of a recent heavy meal, a cold drink, or vere anæmia can be excluded, they may be taken as idence of coronary insufficiency. There is little to oose between the exercise test and the anoxæmia test, d the two are probably best used in conjunction.[9] tisfactory electrocardiograms are less easy to obtain after exercise; on the other hand, the anoxæmia test has caused unpleasant and even dangerous effects, although its advocates believe it to be safe enough provided that a supply of 100% oxygen is immediately available.

Clearly, both tests have disadvantages, especially since negative results do not exclude angina pectoris; but they have a definite place in diagnosis. Turner and Morton suggest that they should be used for those cases of suspected angina without positive signs and where the pain is atypical. They also suggest their use as a method of assessing recovery from myocardial infarction, as a test of fitness for surgical operations, and as an index of the therapeutic action of drugs on the coronary circulation. Nevertheless the limitations of the tests emphasise the importance of adequate history-taking and complete electrocardiographic investigation.

MESENTERIC THROMBOPHLEBITIS MIGRANS

THROMBOPHLEBITIS is a mysterious disorder. Occasionally it manifests itself—nearly always in men under the age of 50—as a series of episodes involving mainly superficial veins but sometimes a vena cava.

North and Wollenman[1] report 3 cases of venous mesenteric thrombosis occurring in series with migratory thrombophlebitis. From their account it is clear that this grave complication has a characteristic clinical picture; and prompt diagnosis and resection of the infarcted segment or segments of gut may be life-saving. A vital clue is the history of an attack, perhaps years previously, of superficial thrombophlebitis with, in about a quarter of the cases, evidence of pulmonary involvement. The actual mesenteric venous thrombosis does not present—like arterial occlusion—as a fulminating catastrophe. The principal disturbance is abdominal pain becoming, over several days, increasingly severe. There is a notable absence of signs of peritoneal irritation, although in the later stages tenderness may be present over the infarcted segment, which is often palpable. The lumen of this segment is not occluded; hence vomiting and distension are inconstant and late. Red blood is often passed per rectum. Operation reveals an imperfectly demarcated infarcted portion of large or small intestine. The veins draining this segment are filled with dark-red thrombi whose uniform age suggests that their extension proximally to the collecting veins is more likely to result from propagation than from intermittent involvement. The arterial bed is not thrombosed.

North and Wollenman point out that resection, while it saves life, has no influence on the disease and further thrombotic episodes are likely. In thrombophlebitis migrans anticoagulant therapy with dicoumarol or ethyl biscoumacetate (‘Tromexan’) should perhaps be continued for many months or even years. The disease may subside as mysteriously as it starts; so the true efficacy of such therapy cannot be gauged.

NUFFIELD CHAIR OF SURGERY: AN APOLOGY

OUR last issue contained an announcement that Professor T. Pomfret Kilner had been appointed to succeed the late Sir Hugh Cairns as Nuffield professor of surgery in the University of Oxford. This announcement was based on a newspaper statement which, though explicit and detailed, was quite incorrect: the position at Oxford remains as it was last October, when we reported that Professor Kilner had been asked to carry on the duties of the Nuffield chair during the current term, and the successor to Sir Hugh Cairns has not yet been chosen. We greatly regret the inconvenience caused by our giving currency to inaccurate information.

The Third Quarter in England and Wales

Provisional figures for England and Wales in the September quarter, 1952,[1] show that the death-rate equalled the lowest ever recorded for the country, while the infant-mortality rate and the stillbirth-rate were the lowest ever recorded

The death-rate was 8 9 per 1000 population The infant-mortality rate was 23 0 per 1000 related live births The stillbirth-rate was 21 5 per 1000 total live and still births The birth-rate was 15 2 per 1000 population—the same as in the September quarter of 1951

The estimated total population of England and Wales at June 30, 1952, was 44,166,000 (21,343,000 male and 22,823,000 female)—an increase of 158,000 over the estimate for 1951

Control of Narcotic Drugs

The control of the Permanent Central Opium Board over the licit movement of narcotic drugs is largely based on the information supplied by the governments producing the raw materials It is the more disturbing therefore that in their report for 1952[2] the board deplore the "vagueness which characterises the statistics of the principal non-producing countries" Thus the total world production of opium is not accurately known, while that of coca leaves cannot be conjectured, because Bolivia and Peru, two of the four producing countries, have never submitted statistics of their production But statistics of the use of these substances for medical and scientific purposes are almost complete, and the board draw attention to the "steady and remarkable increase in the production of codeine during the last two decades" In 1951 for the first time codeine was converted into morphine, 26 kg of codeine produced 18 kg of morphine The board suggest that as a result some change in the control exercised over codeine may be called for The board also point out that though synthetic narcotic drugs are being more widely used than ever there is no decline in the use of the chemical derivatives of opium

Cancer Registration in Denmark

On May 5, 1942, the Danish Cancer Register was inaugurated by the Danish National Association for Combating Cancer, with the support of the Danish public-health authorities, the Danish Medical Association, and other bodies The primary object of this register, the first of its kind organised on a national basis, was to investigate the incidence of malignant disease in Denmark and elsewhere It was to be an endemiological or epidemiological investigation not concerned with the results of the treatment of malignant disease

In his survey of the first ten years, Dr Johannes Clemmesen,[3] who is in charge of the register, points out that all the Danish hospitals send in reports of every case of neoplasm, pathological institutes also send necropsy and histological diagnoses Furthermore, the staff scrutinise all the death certificates for Denmark, so account is taken of the fatal cases of cancer not passing through a hospital

During the past decade studies in Denmark of heredity in relation to malignant disease have suggested that it is easier to establish the influence of heredity on cancer of the body of the uterus than on cancer of the cervix The records of the register show that cancer of the left breast is more common than that of the right breast, in the ratio of 111 to 100, and that close relatives of a patient with breast cancer are more likely to develop disease of the breast on the same side than on the opposite side The register has also disclosed a remarkable rise in the mortality from cancer of the lung in males in Copenhagen, where the death-rate from this cause has risen from 5 per 100,000 population in 1931 to 37 in 1950, in the same period the rate for women has only risen from 4 to 5 per 100,000

In England Now

A Running Commentary by Peripatetic Correspondents

ONE day in the pride of my first house-appointment I overheard a stout lady confide to Sister in a hoarse undertone "Ah want tae see a right doctor Thon's ju a laddie" This balanced judgment, I found, made crystallised into words a fairly general feeling, and many of my associates have subsequently been troubled by the suspicion that I may not, in spite of my now advanced years, be a right doctor Since I embraced academic life the suspicion has, for most of them, hardened into a certainty To the layman, the idea that anyone could voluntarily take such a manifestly wrong turning is a strange one "Do you mean people call you Doctor?" they ask, over the weekly canasta table "Oh" they say, "how odd" And a little silence falls, while they glance furtively at the leather patches on my elbows and then stare speculatively at their own husbands When they get home they tell each other how sad it all is

The neighbours have given us up professionally long ago When we first moved in they used to send their children round, attracted by the prospect of a free medical service just over the fence, and a stand had to be taken. "You see, he's not that kind of doctor," my wife explained, "he does research" "Oh," they say doubtfully, "really?" It is only too clear that they don't believe a word of it They have agreed on a harmless convention whereby they refer to me as Doctor when they think I may be listening, and as Mister when they are reasonably sure I am not

Such a reaction does little to alleviate my own distrust of my rapidly receding clinical acumen As a student I once cut myself badly during an access of zeal for the study of anatomy, and confidently approached my preceptor, an anatomist of twenty years' standing, loaded with higher degrees and fellowships "Oh yes," he said hesitantly, peering into the spurting depths, "that's a nasty one, you'd better see a doctor" With what scorn did I relate this tale to my friends, for from whom should one expect surgical treatment if not from an F R C S? The other day came retribution One of the lab assistants, in the course of an argument with our still, burned his forearm slightly and exhibited the lesion to me "Oh yes," I said hesitantly, "that's a nasty one, you'd better " "No," I said, "on second thoughts, reach me down the first-aid box" He is still alive, and in the limited sphere of the lab there is a growing feeling that I may, despite appearances, be a right doctor after all Only yesterday our histological technician asked me if I would pierce her ears

* * *

The clinicopathological conferences that the students have started are going well An interesting case is chosen, particularly where autopsy material is available, and written up in detail, but with some essential points missing These case protocols are circulated to students and staff two days beforehand, to allow them to wrestle with the case and work out the probable diagnosis Groups of students can be seen in the medical school heatedly debating the differential diagnoses At the C P C the "principal performer," who is a member of the staff selected by the students, reads through the protocol and, by deductive reasoning, attempts to reach the correct diagnosis When he has irretrievably committed himself the audience discuss his conclusions The radiologist then steps forward and shows the films Finally the climax is reached as the pathologist uncovers his specimens and shows his slides, to the triumph or mortification of the speaker The atmosphere is so charged with the competitive spirit that the physician or surgeon who appears enters like a gladiator before the crowd For the students it is an ideal and entertaining way of learning One of them said that it was the first time he had heard a physician thinking logically For the staff it is a somewhat harrowing experience, and even the toughest has shown symptoms of nervous apprehension beforehand

Strong clips attach the guard securely to the element guards.

Fig. 3—Guards for non-reflector electric fires (portable or panel types), attached by means of clips, in such a way that a child could not easily remove them.

electric and gas fire, which could be marketed at a reasonably low price. These new guards are now available, and they will undoubtedly go far to eliminate the most dangerous accidents—those caused by the ignition of clothing and the burning of children's hands. Some of the earliest models were rather unattractive in appearance, but this difficulty has been largely overcome. Moreover it is expected that parents who are concerned about the safety of their children will be willing to make some small sacrifice of æsthetic satisfaction—they will regard a dress-guard as a kind of insurance (and indeed it is so regarded in most other countries). Unfortunately the new guards are not yet widely known, as the firms that have produced them are not in a position to embark upon a nation-wide advertising campaign. This article is written in the hope that many of those connected with the health services—doctors, hospital and district nurses, health visitors, welfare workers, and others—will use such opportunities as they have to make these guards widely known and to encourage their use. It is felt that hospitals, especially, have a responsibility to set an example in this matter. Already a few have acquired guards for the electric fires used in waiting-rooms, side-rooms, sisters' duty rooms, and nurses' homes. It is hoped that all others will follow suit.

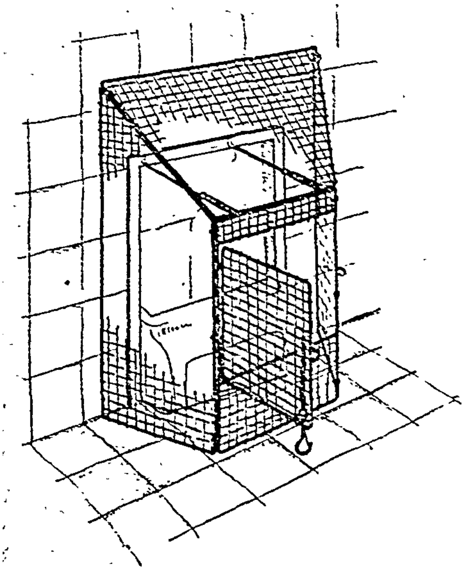

Fig. 4—The Braddell guard.

Is there danger from electric shock associated with the use of these wire guards? As this possibility has sometimes been suggested I have sought expert advice on the point. I was given the following opinions:

(i) Provided the fire is on a proper 3-pin circuit (with nothing disconnected) the use of guards such as those shown in figs. 2 and 3 cannot create any electrical hazard.

(ii) But very often there is some fault in the circuit—e.g., the earth wire is not properly connected up to the socket of the switch, or the earth wire in the plug has got loose, or the wiring of the premises is incorrect, or the earth wire is not connected up properly to a water pipe, &c. In such a case *any* electric fire carries a shock hazard—and the presence of a wire mesh guard will not materially increase it.

(iii) The risk of thermal burning injury associated with an unguarded fire is so much greater than that of electric shock that the balance of advantage is quite clearly in favour of guarded fires.

In view of the possible risks referred to under (ii) both the makers (whose names are given below) emphasise that their guards should be fitted by a competent person, and give explicit instructions as to how they should be fixed.

Guards for reflector types of electric fires appear in fig. 2, and for non-reflector (portable or panel) types of electric fire in fig. 3. Actually the guard shown in fig. 2(*b*), which is made in several sizes, can also be used for non-reflector types. In such cases the guard can be fixed by passing the curtain wires through the horizontal bars usually provided in front of the element and hooking them (with the help of a button-hook) into the front wires of the guard. This method of fixing has the advantage that a child would have more difficulty in removing the guard than when the curtain wire is simply carried round the back of the fire.

GUARDS FOR GAS-FIRES

The guards shown in fig. 2(*b*) and fig. 3 can be applied to those types of fixed gas-fire which carry one or more horizontal bars across the front to which the springs or curtain-wire can be attached. For some of the portable gas-fires (reflector types) at present on the market the guards shown in fig. 2(*b*) will be applicable. In other cases it is hoped that the makers of standard models of gas radiants will be able to supply an appropriate guard.

GUARDS FOR COAL-FIRES

There are so many types of coal-fire—the old-fashioned kitchen range, the bowl fire so widely used in living-rooms, and the closable type of slow-combustion stove—that it would seem to be impossible to design a guard which will be applicable to all of them. And many of the guards which have been on the market in the last fifty years are clearly not very suitable for their purpose.

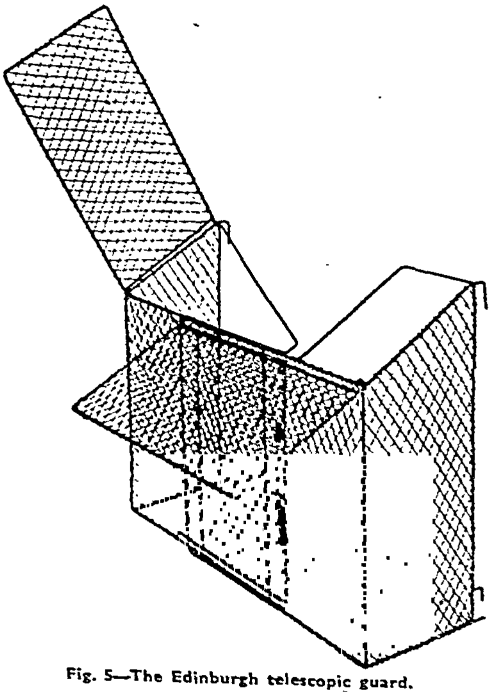

Fig. 5—The Edinburgh telescopic guard.

depression may be well worth while from the patient's standpoint Is he dismayed in a reactive or psychoneurotic way, or is his depression of a kind that might be expected to respond quickly to appropriate psychiatric treatment? In this connection "labels" such as psychosis, endogenous depression, and involutional melancholia still retain a certain meaning Even more urgently is the patient so "depressed and worried about himself" that he may feel prompted to take his life?
